Abstract

**Background:** It is unknown whether a conservative approach to fluid administration or deresuscitation (active removal of fluid using diuretics or renal replacement therapy (RRT)) is beneficial following haemodynamic stabilisation of critically ill patients.

**Purpose:** To evaluate the efficacy and safety of conservative or deresuscitative fluid strategies in adults and children with acute respiratory distress syndrome (ARDS), sepsis, or systemic inflammatory response syndrome (SIRS) in the post-resuscitation phase of critical illness.

**Methods:** We searched Medline, EMBASE, and the Cochrane central register of controlled trials from 1980 to June 2016, and manually reviewed relevant conference proceedings from 2009 to the present. Two reviewers independently assessed search results for inclusion and undertook data extraction and quality appraisal. We included randomised trials comparing fluid regimens with differing fluid balances between groups, and observational studies investigating the relationship between fluid balance and clinical outcomes.

**Results:** 49 studies met inclusion criteria. Marked clinical heterogeneity was evident. In a meta-analysis of 11 randomised trials (2051 patients) using a random effects model, we found no significant difference in mortality with conservative or deresuscitative strategies compared to a liberal strategy or usual care (pooled risk ratio [RR] 0.92, 95% confidence interval [CI] 0.82-1.02, I²=0%). A conservative or deresuscitative strategy resulted in increased ventilator-free days (mean difference 1.82 days, 95% CI 0.53 to 3.10 days, I²=9%) and reduced length of ICU stay (mean difference -1.88 days, 95% CI -0.12 to -3.64 days, I²=75%) compared to a liberal strategy or standard care.

**Conclusions:** In adults and children with ARDS, sepsis or SIRS, a conservative or deresuscitative fluid strategy results in increased number of ventilator-free days and decreased length of ICU stay compared with a liberal strategy or standard care. The effect on mortality remains uncertain. Large randomised trials are needed to determine optimal fluid strategies in critical illness.

**Keywords:** Fluid therapy; Diuretics; Water-electrolyte balance; Critical Illness; Sepsis; Respiratory Distress Syndrome, Adult; Systemic Inflammatory Response Syndrome.
Background

Optimising fluid status is a fundamental concern of critical care practice. Ample data suggest that the optimisation of intravascular volume status can increase cardiac output and global oxygen delivery, and large volumes of intravenous fluids are often administered for this purpose. In addition, critically ill patients frequently receive large volumes of fluid as drug diluents, as artificial nutrition, and as maintenance fluid.

In the face of increased capillary permeability, sodium and water retention, and acute kidney injury (AKI), all of which are common in critical illness, the accumulation of large volumes of fluid in the interstitium is a frequent occurrence and may impair oxygen delivery at the cellular level. Clinically this fluid overload is apparent as peripheral and pulmonary oedema, although other organs may be affected [1]. A number of cohort studies have demonstrated an association between fluid overload and mortality [2-4], and it has been suggested that strategies aimed at prevention or treatment of fluid overload may be beneficial following haemodynamic stabilisation [5].

A previous systematic review and meta-analysis on the topic of fluid overload and the relationship between fluid balance and mortality [6] in critically ill patients reported studies with considerable heterogeneity in design, presence of comparator groups, populations, as well as the timing and nature of interventions. By narrowing our focus to specific populations, and by including but not attempting to meta-analyse observational studies, we aimed to maximise both the external and internal validity of our review.

The aim of this review is to evaluate the impact of a conservative fluid or active deresuscitation strategy compared with standard care or a liberal fluid strategy in critically ill adult or paediatric patients with sepsis, systemic inflammatory response syndrome (SIRS), or acute respiratory distress syndrome (ARDS) on mortality and other clinical outcomes. Secondary aims were to identify criteria used to judge suitability for conservative fluid management or deresuscitation; to describe the interventions used to minimise fluid intake or deresuscitate patients, and to identify contraindications to deresuscitation or conservative fluid management in published studies.

Methods

The protocol for this review was prospectively registered with PROSPERO (International prospective register of systematic reviews; CRD42013005608) and published previously [7]. We used Cochrane review methodology [8] in protocol development and review conduct, and adhered to the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines [9] in reporting the review.

Search strategy

MEDLINE, EMBASE and the Cochrane Central register of controlled trials (CENTRAL) were searched (up to 24th June, 2016) for potentially relevant studies without language constraints. In addition, we manually searched indexed abstracts from the American Thoracic Society, Society of Critical Care Medicine, and European Society of Intensive Care medicine annual congresses and the International Symposium on Intensive Care and Emergency Medicine from 2009 to the present. A full list of MEDLINE search terms is available as an appendix to the published protocol [7].

Inclusion and exclusion criteria

We included randomised and quasi-randomised clinical trials of adult or paediatric patients with ARDS, SIRS or sepsis in which two or more fluid strategies were compared and in which fluid balance differed between groups; and observational studies in which the relationship between fluid balance and clinical outcomes in ARDS, SIRS or sepsis was the major focus of the study.

We excluded studies that focused only on the resuscitation phase of critical illness, and studies in which fluids were only one element of a complex haemodynamic strategy. We also excluded case series, case reports, observational studies with fewer than 50 participants, studies published prior to 1980, studies involving predominantly neonates, post-cardiac surgery patients, or patients with heart failure, and studies subject to post-publication retraction or investigation.
Selection of studies and data extraction

Titles and abstracts of all reports identified in the literature searches were screened by two of three authors (JS, EEM and AF) for further review with discrepancies resolved by consensus. Full text review of eligibility was conducted by two authors independently (JS and EM) and relevant data extracted in duplicate from included studies to a standard piloted form [7]. Discrepancies were resolved by discussion and adjudication by a third author (EF). Where relevant, attempts were made to contact authors of randomised studies for missing data. The reference lists of included randomised trials were reviewed for additional trials meeting eligibility criteria.

Outcome measures

The primary outcome was all-cause mortality at the latest time point available up to 90 days. Key secondary outcomes included ventilator-free days (VFDs), length of intensive care unit (ICU) stay, incidence of AKI, renal replacement therapy (RRT) use, and cognitive impairment.

Risk of bias assessment

Two authors (JS and EM) independently assessed risk of bias and quality. Randomised controlled trials were assessed as being at low, uncertain or high risk of bias for each of 6 domains using the Cochrane risk of bias tool [8]. Cohort and case-control studies were assessed for quality using the Newcastle Ottawa scale [10] (Appendix 2).

Analysis

RevMan software [8] was used to carry out meta-analysis using a random effects model for outcomes for which two or more randomised studies were available. Results for outcomes for which meta-analysis was deemed inappropriate because of an insufficient number of studies or clinical or statistical heterogeneity were reported in narrative form, and observational studies were reported in tabular form (Appendix 1). Where necessary to standardise reporting of central tendency between studies, we converted standard error to standard deviation, and estimated mean and standard deviation from reported median and interquartile ranges using a standard approach [11]. For key outcomes, we assessed the quality of evidence using the Grades of Recommendation, Assessment, Development and Evaluation (GRADE) approach [12].

We undertook a pre-planned sensitivity analysis excluding studies at high risk of bias, and subgroup analyses for ARDS, sepsis or SIRS, and adults. We also undertook a post-hoc analysis in which we excluded studies lacking a clinically-significant difference in fluid balance between groups, which we defined as a minimum difference in mean or median fluid balance of 750 mL per day for adults or 10 mL/kg/day for children. We also carried out a meta-regression analysis with difference in mean daily fluid balance as the independent, and risk ratio (RR) for mortality as the dependent variable.

Results

The search was conducted up to 24 June 2016 and during the editorial process we obtained one further study in press from the editor. Forty-nine studies met criteria for inclusion. Of these, 11 randomised controlled trials, recruiting a total of 2051 patients, provided data for meta-analysis. The remaining 38 studies were observational in design and are summarised in Appendix 1. The Newcastle-Ottawa score for observational studies is reported in Appendix 2. Secondary publications from included studies are reported along with the original study [13-15]. A summary of evidence is found in Table 2.

Description of included randomised trials

Considerable clinical heterogeneity was present. Five studies [16-20] took place in the United States, three in China [21-23], one in France [24] one in India [25] and one in Denmark and Finland [26]. Sample sizes ranged from 29 [21] to 1000 [16]. One was conducted in children [25] and the remainder in adults. Five studies included only patients with ARDS [16-18, 21, 22], four included only patients with septic shock [19, 24-26]; one included patients with ARDS, septic shock, or both [23] and one included a mixed critically ill
population, the majority of whom had sepsis, ARDS, or both [20]. Further characteristics of included randomised trials are presented in Table 1.

**Methodological quality and risk of bias**

The overall quality of included randomised trials was moderate (Figure 2). The use of random sequence generation and allocation concealment [19-22, 25] and the risk of reporting bias [18, 20-22, 25] were unclear in a number of studies. While blinding was used in only 2 studies [17, 18], likely due to difficulties in concealment of the different fluid regimens and/or haemodynamic monitoring technologies employed, strict protocolisation of fluid and diuretic use was felt to ameliorate the effects of this potential bias in all but two studies [19, 21].

**Mortality (primary outcome)**

Eleven studies (2051 patients) reported mortality as an outcome with variable duration of follow-up, including 90-day [26], 60-day [16, 21, 22], in-hospital [19, 20] and 28 or 30-day mortality [17, 18, 23-25]. We found no significant difference in mortality between patients receiving a conservative or deresuscitative fluid strategy compared with those receiving a liberal strategy or standard care (pooled RR 0.92; 95% confidence interval [CI] 0.82-1.02, I²=0%) (Figure 3).

One trial [16] accounted for the majority of patients in the ARDS subgroup, and the results for this subgroup (5 studies, n=1206, pooled RR 0.91; 95% CI 0.77-1.07) were similar to those in the overall analysis. In the sepsis/SIRS subgroup, three trials were conducted in adults [19, 24, 26] and one in children [25]. Results from this subgroup analysis were also similar to those in the overall analysis (394 patients, pooled RR 0.86; 95% CI 0.62-1.17) (Figure 3).

**Secondary outcomes**

**Ventilator-free days**

Data on the number of VFDs within a 28 or 30-day period were available for seven studies, including 1784 participants (Figure 4). We found increased VFDs with a conservative or deresuscitative fluid strategy in comparison with a liberal strategy or standard care (mean difference 1.82 days [95% CI interval 0.53 to 3.10 days], I²=9%). In addition, studies by Hu et al [21] and Wang et al [22] reported shorter duration of mechanical ventilation in a more conservative fluid strategy group compared with the liberal fluid strategy group (10.13 +/- 3.02 days vs. 12.64 +/- 2.89, P<0.05 and 9.62 +/- 2.55 days vs 12.51 +/- 2.92 days, P<0.05 respectively).

**Length of ICU stay**

Nine studies reported the duration of ICU admission of which seven were suitable for meta-analysis (Figure 5). We found a shorter length of ICU stay in patients receiving a conservative or deresuscitative fluid strategy compared with those receiving a liberal strategy or standard care (mean difference 1.88 days fewer (95% CI -0.12 to -3.64 days). Considerable heterogeneity was present (I²=75%). Two studies in ARDS patients reported a composite outcome of ICU-free days: Martin et al [18] reported a numerically greater number of ICU-free days in the fluid conservative group (median 1.5 days greater, 95% CI -3.4 to +6.4 days), while in the Fluids and Catheter Treatment Trial (FACTT) [16], a conservative strategy resulted in a significantly greater number of ICU-free days compared to a liberal strategy (13.4 +/- 8.97 versus 11.2 +/- 8.92, P<0.001).

**Length of Hospital stay**

One study [18] reported no significant reduction in the length of hospital stay for survivors of ARDS with a deresuscitative strategy (median 4.5 fewer days in hospital, 95% CI -5.8 to 14.8 days).

**Organ dysfunction scores**

Martin et al [17] reported a fall in mean Sequential Organ Failure Assessment (SOFA) score of 0.6 with a deresuscitation strategy compared with an increase of 1.1 in the control group over the 5 day study period (P=0.01). Zhang et al [23] reported higher maximum SOFA scores in the more conservatively managed group, although this difference was also present at baseline; and Richard et al [24] reported similar duration of SOFA score ≥ 6.
Long-term mortality
No studies reported long-term (>90 day) mortality as an outcome.

Incidence of ARDS
No studies reported incidence of ARDS as an outcome.

Incidence of Acute Kidney Injury
Martin et al [18] reported no difference in change in serum creatinine between patients in a deresuscitation group compared with placebo, while in the FACTT study [16] the incidence of AKI was similar between conservative and liberal fluid management groups (21.5 +/- 11.21 renal failure free days versus 21.2 +/- 11.15, P=0.59). Hjortrup et al [26] reported a lower incidence of worsening of AKI in a conservative fluid group than with standard care (37% versus 54%, P=0.03). In separate post-hoc analyses of the FACTT study, Liu and colleagues showed that after correcting serum creatinine levels for fluid balance, AKI incidence was lower with a conservative than with a liberal fluid strategy [14]; and Grams et al reported that in patients with AKI, cumulative diuretic dose was independently associated with lower mortality [15].

Renal replacement therapy use
In three studies [16, 19, 26] (1233 patients), the rate of RRT use was similar between patients receiving a conservative fluid or deresuscitative strategy compared with a liberal fluid strategy or standard care (RR 0.88; 95% CI 0.64-1.22, I²=27%) (Appendix 3.5). Zhang et al [23] reported fewer days free of continuous RRT in the conservative fluid strategy group (median 15.5 days [IQR 3-28] versus 21 [4-28], P<0.05).

Cognitive function
In a cohort of seventy-five survivors from FACTT [16] who underwent follow up assessment of cognitive function, Mikkelsen et al [13] identified enrolment in the conservative fluid management arm as an independent risk factor for cognitive impairment at twelve months post hospital discharge. In contrast, Wang and colleagues [22] assessed post-ICU cognitive function as one component of the QLQ-C30 quality of life score, and found better cognitive function scores in patients treated with a conservative fluid strategy than a liberal fluid strategy (85.02 +/- 15.06 vs. 74.31 +/-12.88, P<0.05).

Additional analyses
Additional sensitivity and subgroup analyses are found in Appendix 3.

Readiness for conservative fluid management or deresuscitation
The majority of studies did not attempt to use specific physiological or time criteria to determine readiness for conservative fluid management or deresuscitation. One study [19] postponed initiation of a conservative fluid management strategy until patients were demonstrated to be volume unresponsive. Fluid minimisation occurred between one and four days post-randomisation, however clinically-significant separation of fluid balance between groups was not achieved over five days.

Interventions
There was considerable variation in fluid strategies applied and fluid balances achieved in both conservative / deresuscitative and liberal / standard care groups. In three studies [16-18], protocolised diuretic use was used in the conservative / deresuscitative arm, in four the intervention strategy involved protocolised fluid restriction or minimisation [16, 19, 25, 26]; and in five the main intervention was the use of alternative haemodynamic targets for fluid management, based on extravascular lung water (EVLW) [20-22], pulse pressure variation (PPV) [24], or intrathoracic blood volume index (ITBVI) [23]. In two trials hyperoncotic albumin infusions were used to potentiate diuresis in a deresuscitative group [17, 18]. Fluid strategies in study control arms included protocolised liberal fluid administration [16], protocolised diuretic use without hyperoncotic albumin [17] and central venous pressure (CVP) or pulmonary capillary wedge pressure (PCWP)-guided fluid administration [20, 21, 23, 24].

As a result of variability in fluid strategies used, there was wide variation in fluid balances and considerable overlap between conservative and liberal groups. For example, in the study by Martin et al [17] the ‘liberal’ group received diuretics and achieved a weight loss of 4700 mL over five days, equating to an estimated mean fluid balance of -22.4 mL/kg/day; while in the study by Chen and Kollef [19], a targeted fluid...
minimisation strategy in the conservative arm yielded a median positive fluid balance of 2641 mL over five
days, equating to a positive mean fluid balance of 7.5 mL/kg/day.

Contraindications to deresuscitative fluid management

Two studies of deresuscitation [17, 18] excluded patients with AKI, those with more than a minimal
requirement for vasopressors, and those with uncorrected hypernatraemia or hypokalaemia.
Deresuscitation was suspended if hypotension, hypernatraemia or hypokalaemia developed during the
intervention period, and fluid boluses were given at the discretion of the clinical team. In FACTT [16], fluid
administration and diuretic use was protocolised, so that haemodynamic insufficiency triggered fluid bolus
administration or vasoactive medication use, and diuretics were withheld in the presence of AKI.

Observational studies

We included a total of 38 observational studies in this review; characteristics are reported in appendix 1.
The majority were cohort studies in which fluid balance was compared between survivors and non-
survivors of critical illness, with or without adjustment for severity of illness and other potential confounders.
The majority of observational studies were assessed as moderate or low quality using the Newcastle-
Ottawa scale (Appendix 2).

The main finding was a consistent positive association between more positive fluid balance and higher
mortality [3, 4, 27-52] which was present within all pre-specified subgroups: adults [3, 4, 28, 30-33, 36-38,
40-46, 48, 50-53], children [27, 29, 35, 49], ARDS [3, 32, 35, 39, 40, 43, 46, 48, 49] and sepsis [4, 27-31,
33-38, 40-42, 44, 45, 50-53]. This association was absent or present only in subgroups in seven studies in
which mortality was reported as an outcome [54-60]. One study reported a lower mortality with greater fluid
administration and more positive fluid balance over 3 days [61]. A more positive fluid balance was
associated with increased [32, 55] or similar [29, 42] duration of mechanical ventilation, fewer ventilator-free
days [35, 54, 56, 60] and increased [32, 52, 60] or similar [42, 55] length of ICU stay. Rates of AKI or RRT
use were similar [29, 33, 56, 59, 61, 62] or higher [36, 60] with a more positive fluid balance.

Discussion

Although reference is made in current guidelines to the use of intravenous fluid for resuscitation in sepsis
[63], fluid management goals following the resuscitation phase of critical illness remain the subject of
considerable uncertainty. Our review evaluated the efficacy and safety of a conservative or deresuscitative
fluid strategy compared with standard care or a liberal fluid strategy in critically ill patients with sepsis,
SIRS, or ARDS.

We found no clear evidence for the superiority of one fluid strategy over another for our primary outcome of
mortality. This is in contrast to a previous meta-analysis [6], and likely reflects our exclusion of
observational data from our meta-analysis. We found that a conservative or deresuscitative fluid strategy
resulted in a greater number of VFDs and decreased length of ICU stay than a liberal fluid strategy or
standard care, with no increase in acute kidney injury, use of RRT, or cognitive dysfunction. When we
excluded those studies in which we considered inter-group differences in fluid balance to be clinically
unimportant, we found a non-significant reduction in mortality with conservative or deresuscitative fluid
management (Appendix 3.3). The quality of evidence was low or very low across all outcomes.

We found no difference in rates of renal replacement therapy use between fluid strategies. Along with post-
hoc analyses of the FACTT study showing a reduced incidence of AKI with a conservative fluid strategy
[14] and a protective effect of diuretic use [15], this provide reassurance as to the safety of a conservative
or deresuscitative approach to fluid management in terms of renal outcomes.

The effect of a conservative fluid strategy or deresuscitation in terms of cognitive outcomes is unclear, with
a secondary analysis of a small cohort of patients from the FACTT study showing evidence of harm from a
conservative approach [13]. This contrasts with the findings of Wang and colleagues in which post-ICU
discharge cognitive function was improved in a conservative fluid management group [22], and those of a
small randomised trial in patients undergoing major vascular surgery where a conservative fluid strategy
was associated with a reduction in post-operative complications including delirium [64], a clinical outcome
known to be associated with longer term cognitive dysfunction [65]. This merits further investigation in future trials investigating fluid strategy.

Our review has a number of strengths. It was conducted using high quality systematic review methodology. A highly sensitive search strategy was developed which was independently reviewed by a second information specialist. In order to minimise bias, no language restrictions were employed, and broad date criteria were applied. At least two reviewers were involved independently at each stage of the review process, and all studies were evaluated for quality and risk of bias.

There are a number of important limitations in this review, however. Even in the small number of studies included, considerable heterogeneity was evident with respect to study populations, interventions, and outcomes. Due to lack of standardised definitions, the timing and duration of the ‘post-resuscitation’ intervention period varied between studies, although the available data did not allow in-depth exploration of this issue. This highlights the need to standardise these definitions for future clinical trials. Because of insufficient data, we were unable to separate the differential impact of restrictive fluid administration and active deresuscitation. Some of the interventions employed resulted in minimal separation between groups in fluid balance. As we did not define what constituted a clinically-significant difference in fluid balance between groups a priori, we included all in our main analysis (Figure 3) but undertook a sensitivity analysis in which studies were excluded on the basis of clinically insignificant differences in fluid balance between groups (Appendix 3.3).

There was considerable inconsistency in reporting which precluded some studies for inclusion in meta-analyses, exemplified by some studies reporting duration of mechanical ventilation with others reporting a composite outcome of ventilator-free days. This is a recognised problem in studies of patients receiving mechanical ventilation [66]. Even for the uniformly reported outcome of mortality, there was variability in the duration of follow-up from 28 to 90 days, although this is unlikely to have had a major impact on summary estimates of effect [67].

We limited our review to patients with sepsis, SIRS and ARDS. The inevitable consequence is a loss of generalizability to other types of critically ill patients, although since these are common syndromes rather than specific diagnoses, and since patients admitted to ICU with a range of pathologies (e.g. traumatic brain injury [68] and polytrauma [69]) frequently develop SIRS, ARDS and sepsis, the generalizability of these findings is likely go beyond simply those patients who meet rigidly applied consensus criteria.

We identified a large number of observational studies in which fluid accumulation or overload was associated with worse outcomes, particularly mortality. The potential for residual confounding is present to some extent in all of these, in that greater cumulative fluid balances may reflect greater severity of illness and greater perceived or actual need for fluid resuscitation or clinician reluctance to either withhold fluid or to administer diuretics to more severely ill patients.

Robust multicentre trials are needed to evaluate the effectiveness of restrictive fluid administration, deresuscitation or a combined fluid strategy to improve patient outcomes. Based on our data, a sample size of over 4700 patients would be required to detect or exclude a significant mortality benefit for a conservative and/or deresuscitative fluid strategy (Appendix 3.3). However, the heterogeneity illustrated in this review highlights the need for considerable further pilot work to define the optimal intervention strategy or strategies to be subsequently tested in high-quality, adequately powered multicentre randomised trials. Pilot studies should, for example, address the questions of physiological or other criteria to define the appropriate timing for conservative fluid management, the utility of deresuscitation in addition to fluid restriction alone, the comparative benefits and harms of ultrafiltration and diuretics, and the use of adjunctive hypertonic albumin among others.

Conclusions

Despite a considerable body of observational evidence showing a positive association between fluid balance and mortality, our review found no significant difference in mortality from included randomised trials addressing the question of optimal fluid strategy for critically ill patients. We found that a conservative or deresuscitative approach resulted in increased ventilator-free days and decreased length of ICU stay compared to a liberal strategy or standard care.
Large robust trials are needed in which clear inter-group differences in fluid balance are present to evaluate the efficacy and safety of a conservative or deresuscitative fluid strategy in terms of both short and long term outcomes. The optimum strategy to be tested in such trials remains to be defined. Meanwhile, clinicians caring for critically ill patients may consider the use of a conservative fluid management strategy in patients with sepsis, ARDS and SIRS following initial resuscitation and stabilisation.

| 2005 | Two academic centres in United States | Inclusion criteria:  
- ARDS  
- Serum total protein < 6 g/dL | Exclusion criteria:  
- Haemodynamic instability  
- Renal disease or cirrhosis  
- Age < 18 years  
- Pregnancy  
- Serum sodium > 155 mmol/L or potassium < 2.5 mmol/L | Followed by infusion, and 25g IV albumin 8 hourly for 3 days  
- Mean net fluid balance after 3 days was -5480 ml*  
- Mean daily fluid balance over study period: -15.7 ml/kg/day | Followed by infusion, with 0.9% saline placebo for 3 days.  
- Mean net fluid balance at 3 days was -1490 ml*  
- Mean daily fluid balance over study period: -4.3 ml/kg/day | - Ventilator-free days  
- Change in SOFA scores |
| Wiedemann et al, 2006 | RCT  
Multiple community and academic ICUs in United States and Canada | Inclusion criteria:  
- ARDS  
- Intubated and mechanically ventilated  
- Presence or intention to insert a central venous catheter | Exclusion criteria:  
- Presence of ALI/ARDS for > 48 hours  
- Severe chronic illness likely to independently influence survival  
- Irreversible terminal illness | Complex algorithm with fluid boluses or diuretics administered as directed by filling pressures (CVP or PCWP).  
- 41% of protocol instructions involved administration of furosemide, 6% involved fluid boluses  
- At 7 days, net fluid balance was -136 ml +/- 11012 ml*  
- Mean daily fluid balance over study period: -0.3 ml/kg/day | Complex algorithm with fluid boluses or diuretics administered as directed to target higher filling pressures (CVP or PCWP) than in conservative group.  
- 10% of protocol instructions involved administration of furosemide, 15% involved fluid boluses  
- At 7 days, net fluid balance was 6992 ml +/- 11191 ml*  
- Mean daily fluid balance over study period: 14.3 ml/kg/day | - 60-day mortality  
- Ventilator-free days  
- ICU-free days  
- Renal failure-free days  
- RRT use  
- CNS failure-free days |
| Hu et al, 2014 | RCT  
Single centre in China | Inclusion criteria:  
- ALI/ARDS (AECC criteria)  
- Admitted to ICU | Extravascular lung water target value set at 3-7 ml/kg, using diuretics or CRRT  
- Fluid administration not protocolised | Pulmonary artery occlusion pressure target of 8-12 mmHg, using diuretics or CRRT  
- Fluid administration not protocolised |  
- 60-day mortality  
- Duration of mechanical ventilation  
- Length of ICU stay |

Table 2. GRADE Summary of findings table for key outcomes. **CI:** Confidence interval; **RR:** Risk ratio; **MD** Mean difference. Explanatory notes: 1. Only five studies were at low risk of bias, the remainder were at moderate or high risk of bias. 2. Significant variability in populations, interventions and comparators studied. 3. Only two studies were at low risk of bias, the remainder were at moderate or high risk of bias. 4. Considerable heterogeneity present across studies ($I^2=75\%$). 5. Insufficient number of participants to exclude clinically important benefit or harm. 6. Single study, uncertain risk of bias across all domains. 7. Limited available information on intervention strategy.

Appendix 2. Modified Newcastle-Ottawa scale for included cohort studies.

Selection:

1) **Representativeness of the exposed cohort**
   a) truly representative of the average ARDS / SIRS / sepsis population in the community □
   b) somewhat representative of the average ARDS / SIRS / sepsis population in the community
   c) selected group of patients
   d) no description of the derivation of the cohort

2) **Selection of the non exposed cohort**
   a) drawn from the same community as the exposed cohort
   b) drawn from a different source
   c) no description of the derivation of the non exposed cohort

3) **Ascertainment of exposure**
   a) secure record (eg surgical records)
   b) structured interview
   c) written self report
   d) no description

4) **Demonstration that outcome of interest was not present at start of study**
   a) yes
   b) no

Comparability:

1) **Comparability of cohorts on the basis of the design or analysis**
   a) study controls for severity of illness
   b) study controls for haemodynamic status

Outcome:

1) **Assessment of outcome**
   a) independent blind assessment
   b) record linkage
   c) self report
   d) no description

2) **Was follow-up long enough for outcomes to occur**
   a) yes
   b) no

3) **Adequacy of follow up of cohorts**
   a) complete follow up - all subjects accounted for
   b) subjects lost to follow up unlikely to introduce bias > 98 % follow-up or description provided of those lost
   c) follow up rate < 99%and no description of those lost
   d) no statement

Heterogeneity: $I^2 = 0.00$, $Q = 0.48$, $df = 4$ ($P = 0.48$); $I^2 = 0$

Test for overall effect: $Z = 1.34$ ($P = 0.18$)

3.1 Pre-planned sensitivity analysis excluding studies at high or moderate risk of bias with mortality as outcome.
3.2 Pre-planned subgroup analysis including only adult studies with mortality as outcome.
3.3 In a post-hoc sensitivity analysis in which we excluded studies lacking a clinically-important separation in fluid balance between groups, we found a non-significant reduction in mortality with a conservative or deresuscitative strategy compared to a liberal strategy or standard care.

We used these findings to calculate the required sample size to test the hypothesis that conservative fluid management or deresuscitation strategy reduces mortality compared to a liberal strategy or standard care. Based on a 13% relative risk reduction (assuming a comparable difference in mortality to those studies in which a clinically-significant difference in fluid balance was achieved), a baseline mortality risk of 34%, two-tailed alpha of 0.05 and power of 90%, we calculated this to be 4704 patients.
3.4 Univariate meta-regression analysis with RR for mortality as dependent variable and between-group difference in mean daily fluid balance as exposure. 
\( R^2 = 0.11, P = 0.30 \)
3.5 Forest plot for renal replacement therapy use, conservative or deresuscititative fluid strategy versus standard care or liberal fluid strategy.
