Centre for Theoretical Atomic, Molecular and Optical Physics, Queen’s University Belfast, Belfast BT7 1NN, United Kingdom

We report on calculations of harmonic generation by neon in a mixed (800-nm + time-delayed 400-nm) laser pulse scheme. In contrast with previous studies we employ a short (few-cycle) 400-nm pulse, finding that this affords control of the interference between electron trajectories contributing to the cutoff harmonics. The inclusion of the 400-nm pulse enhances the yield and cutoff energy, both of which exhibit a strong dependence on the time delay between the two pulses. Using a combination of time-dependent R-matrix theory and a classical trajectory model, we assess the mechanisms leading to these effects.

I. INTRODUCTION

The process of high-order-harmonic generation (HHG) has been the driving force behind countless new developments in ultrafast laser technologies over the past decade. HHG has been used to create both short-duration [1] and high-energy [2] laser pulses and can also be used directly in atomic [3] and molecular spectroscopy [4] to elucidate the attosecond-scale dynamics of electrons.

HHG is commonly described by the classical three-step model in which an electron (i) tunnels through the laser-suppressed Coulomb barrier, (ii) is accelerated by the field, and (iii) recombines with its parent atom emitting a high-energy photon, all within a single cycle of the driving laser field [5]. Analysis of the electron motion reveals two classes of trajectory. The so-called long and short trajectories represent two distinct pathways leading to the same recollision energy. Importantly, the cutoff (highest) energy trajectories arise when the long and short trajectories coalesce. It has been shown that interference between these pathways leads to an Airy pattern in the harmonic plateau [6].

The study of spectral caustics in HHG is an extension of this interference effect. Caustics arise in the analysis of ray optics: where multiple rays coalesce a sharp peak, or caustic, appears in the emitted radiation. This enhancement is predicted by catastrophe theory, and is due to a singularity in the spectral density. In HHG, caustics result from the coalescence of more than two electron trajectories in the same spectral region, which can be engineered by adding a second color to the driving laser pulse. The second color breaks the symmetry of the process, splitting the electron trajectories into two further classes. The so-called upper and lower branch trajectories (named as they yield higher or lower cutoff energies than the equivalent one-color trajectories) can then interfere and, when they coalesce at the cutoff energy, yield a dramatic enhancement in the harmonic spectrum [7, 8].

Such interference between trajectories represents an attractive means of probing the quantum nature of the HHG process, which has been understood primarily as a strong-field (classical) process. However, this is experimentally challenging, because the measured harmonic spectrum arises from the coherent response of many atoms and, depending on the experimental conditions, only either the short or long trajectories can be appropriately phase matched. Additionally, in a two-color field, the upper branch trajectories have a reduced ionization and recollision probability relative to the lower branch. Recently, however, it was shown that a shape resonance in the harmonic spectrum can compensate for these factors, and reveal the spectral interference of the relevant trajectories [8].

The manipulation of electron trajectories with two color fields has been realized in various schemes. Schäfer and coworkers proposed the use of a combined infrared (IR) / extreme ultraviolet (XUV) scheme to control the electron trajectories [9]. More recently the XUV-initiated HHG scheme has been applied to monitor core-hole dynamics in small molecules [10], and to elucidate the contribution of both inner and outer valence electrons to the HHG spectrum [11].

A more established technique involves the use of two colors in the visible-IR range, and in particular using a driving pulse and its second harmonic (ω + 2ω) has been well studied. The inclusion of the second harmonic has been shown to enhance the high-harmonic yield [12] and extend the cutoff energy of the harmonic spectrum [13]. Thus, two-color fields have been used extensively for the generation of supercontinua in the XUV range [14, 15], the spectral shaping of attosecond pulse trains [16], and quantum path selection in HHG [17].

In all previous studies, the second harmonic is included as a long-duration dressing field which imparts some phase-dependent effect to the harmonic spectrum. In the present paper we will instead consider the interference between electron trajectories driven by two few-cycle pulses.

We obtain the harmonic spectra using the ab initio time-dependent R-matrix method known as RMT [18]. RMT has been used to investigate various strong-field phenomena, including multielectron correlation in doubly and core-excited states in Ne [19], electron recollision in F− [20], IR-assisted photoionization of Ne+ [21] and HHG from noble gas atoms in the NIR regime [11, 22]. A predecessor to the RMT method was also used extensively to study harmonic generation in a variety of targets in the UV-visible range [23–26]. The RMT approach has two defining capabilities. First, the code is optimized to run on massively parallel (>1000 cores) machines, thus making the extension to challenging physical systems tractable. Second, the RMT approach can be applied to general multielectron systems— including open-shell atoms and ions— with a full description of electron correlation effects.

Here we use the ab initio RMT method to apply a quantitative analysis to spectral caustics in two-color HHG schemes. We first give an overview of the RMT
method and the calculation parameters employed, then present results of calculations of the harmonic spectrum for a neon atom in a combined 800/400-nm pulse scheme.

II. TIME-DEPENDENT $R$-MATRIX THEORY

The $R$ matrix with time-dependence method (RMT) employs the well-known $R$-matrix paradigm of dividing configuration space into two separate regions, in this case over the radial coordinate of an ejected electron. In an inner region (close to the nucleus) all electron-electron interactions are taken into account while in the outer region an ejected electron is sufficiently far from the residual ion that the effect of electron-exchange can be neglected. The most appropriate numerical method for solving the time-dependent Schrödinger equation (TDSE) is employed in each region and, at variance with other $R$-matrix-based approaches, the wavefunction itself is matched explicitly at the boundary rather than via an $R$ matrix [18].

In the inner region the time-dependent $N$-electron wave function is represented over an $R$-matrix basis with time-dependent coefficients. The basis is constructed from the $N-1$ electron-states of the residual ion coupled to a complete set of single-electron functions representing the ejected electron. Additional $N$-electron correlation functions can be added to the basis set to improve the accuracy of the wave function. In the outer region, the wave function is described in terms of residual-ion states coupled with the radial wave function of the ejected electron and is expressed explicitly on a finite-difference grid. The two region wave functions are then matched directly at the boundary in two directions. The outer region finite-difference grid is extended into the inner region and the inner region wave function is evaluated on this grid. This provides the boundary condition for the solution of the TDSE in the outer region. A derivative of the outer region wave function at the boundary is also made available to the inner region, enabling the inner region wave function to be updated. The wave function is propagated in the length gauge, as it has been found to give better results with the atomic structure description employed in time-dependent $R$-matrix calculations [27].

The harmonic spectra are obtained by evaluating the time-dependent expectation value of the dipole velocity, then Fourier transforming and squaring it, thus:

$$\mathbf{d}(t) = \frac{d}{dt}\langle \Psi(t)|cz|\Psi(t)\rangle,$$  

where $\mathbf{z}$ is the total position operator along the laser polarization axis and $\Psi$ is the wave function. It is also possible to calculate the spectra using the expectation value of the dipole length [28], and within our simulations this is used as a check for accuracy. Indeed the spectra produced from each method show excellent agreement with each other until well past the cutoff energy. The spectra shown in the present paper are those calculated from the dipole velocity.

To aid our analysis of the harmonic spectra we perform classical trajectory simulations based on the three-step model [5]. We assume an electron is tunnel ionized into the continuum with zero initial velocity, and, for each possible ionization time, we determine the electrons velocity and position by integrating over the acceleration in the two-color field. We note that this model does not account for any effect of the atomic potential. Trajectories which return again to the origin represent recolliding electrons which give rise to harmonic generation. The energy of this emitted harmonic light can then be calculated from the electrons recollision energy and the ionization potential.

III. CALCULATION PARAMETERS

The neon atom is described within an $R$-matrix inner region with a radius of 20 a.u. and an outer region of 2500 a.u. An absorbing boundary, beginning at 1500 a.u., is included to prevent reflections of the wave function. The finite-difference grid spacing in the outer region is 0.08 a.u. and the time step for the wave-function propagation is 0.01 a.u. The description of neon includes all available 2$s^2$2$p^5$ and 2$s^2$2$p^6$ channels up to a maximum total angular momentum of $L_{\text{max}} = 79$. The inner region continuum functions are constructed using a set of 50 $B$ splines of order 9 for each available angular momentum of the outgoing electron.

We employ a mixed laser pulse scheme comprising a fundamental (800-nm) pulse and its second harmonic (400-nm). In every mixed laser pulse scheme employed the pulses are linearly polarized and parallel. The intensities of the 800 and 400 nm pulses are fixed at $4 \times 10^{14}$ W/cm$^2$ (corresponding to a ponderomotive energy of 24 eV) and $4 \times 10^{13}$W/cm$^2$, respectively. Both pulses employ a $\sin^2$ ramp on/off and are, unless otherwise stated, six cycles in duration (three cycles ramp on, three cycles ramp off). The time delay is measured between the central peaks of the two pulses, and a negative time delay corresponds to the 400-nm pulse arriving first. We increment the time delay in steps of 0.1 fs.

IV. RESULTS

Figure 1(a) shows the harmonic spectra obtained from neon irradiated by a six-cycle 800-nm ($\omega$) pulse and a time-delayed six-cycle 400-nm (2$\omega$) pulse. The inclusion of the 2$\omega$ pulse breaks the symmetry of the three step process, and stimulates the generation of even harmonics [29]. The two-color field also elicits an enhancement of up to four orders of magnitude in the harmonic emission compared to the primary field alone (not shown), particularly in the cutoff region [12]. This is one to two orders of magnitude higher than the enhancement achieved by simply increasing the intensity of the primary field by 10% to match the combined peak intensity of the two-color field.

This enhancement is manifest most clearly in the appearance of the distinctive swallowtail caustics in the cutoff harmonics. These sharp peaks in harmonic emission represent a singularity in the harmonic emission, caused by the coalescence of multiple electron trajectories in the two-color field [7]. Changing the time delay between the $\omega$ and 2$\omega$ pulses changes the phase re-
relationship between the interfering trajectories, shifting the coalescence to higher energy and leading to the two "arms" of the swallowtail. The series of swallowtails which peak at the cutoff energy and decrease in intensity with decreasing harmonic photon energy describe an Airy pattern [6].

The swallowtail caustics are most clearly visible when two short pulses are used [Fig. 1(a)], but the overall yield is increased by the use of a longer $2\omega$ pulse. Figures 1(b) and 1(c) show the spectra produced using a 12-cycle 400-nm pulse. In both cases the 400-nm pulse has a three-cycle $\sin^2$ ramp on and off, with six cycles at peak intensity (3-6-3); in Figure 1b the 800-nm pulse has a 3-3 form while in Fig. 1c it has a 2-2-2 form. Using a long $2\omega$ pulse is more similar in spirit to previous studies in this field, where the second harmonic can be treated as a dressing field which imparts a phase dependent enhancement or suppression on the harmonic yield [12–17].

Using a long $2\omega$ pulse yields an increase in harmonic emission relative to the short-$2\omega$-pulse spectrum in Fig. 1(a). The $2\omega$ field is present for the duration of the 800-nm pulse, and thus affects electron trajectories originating earlier or later in the fundamental pulse. Thus the emission is also less concentrated in the cutoff region such that the entire plateau is enhanced. Furthermore, the interference patterns in the time-delay spectra are strongly modified by the shape of the pulses. Changing from a 3-3 to a 2-2-2 pulse shape is similar to broadening the carrier envelope of a Gaussian 800-nm field: with this profile there is no longer a single central peak. Thus each harmonic energy is sourced by trajectories on multiple cycles, and the interference between them appears as the comblike fringes in Fig. 1(c). The arms of the swallowtail caustic are still visible in the cutoff region, but the singular enhancement at the point of the caustics is somewhat bleached by the overall increase in the harmonic yield. Changing the pulse profile also has the effect of shifting the caustic to higher energy, as shown in Fig. 2, because the trajectories leading to the caustic are now driven by higher intensity cycles of the 800-nm pulse. For the same reason, the swallowtail caustic which appears for a delay of $\approx -0.5$ fs in Figs. 2(a) and 2(b) is at higher energy than the main caustic at $\approx +0.17$ fs: the particular half cycle of the 800-nm pulse which drives the cutoff trajectories is stronger, as depicted in Fig. 3(c) compared with Fig. 3(d).

Using a profile with a single central peak yields two different interference structures in the cutoff harmonics in Fig 1(b)—a long smeared out finger extending to high energy and a lower-energy comb-like interference pattern.

We suggest the following interpretation of these interference structures in the strong-field context. The highest-energy trajectories are launched when a (peak) trough of the $2\omega$ field arrives just after a trough (peak) of the $\omega$ pulse i.e., when the vector potentials of the two fields are oppositely oriented (unshaded regions in Fig. 3). In a short pulse, the highest-energy trajectories are launched from each half cycle prior to the central peak (Fig. 3(c): black dot). Therefore, for delays where a peak of the 400-nm pulse arrives just after the penultimate trough of the 800-nm pulse, there is one trajectory with the highest return energy, which manifests as broad harmonic peaks at the cutoff [22], and appears as the long smeared out fingerlike feature in Fig. 1(b).

By contrast, if troughs of the 400-nm pulse occur just after the penultimate and main peaks of the 800-nm pulse, trajectories of approximately equal return energy are launched from each (Fig. 3(d): black dots). Interference between harmonic light generated by the
two trajectories yields a comb-like interference pattern. This picture is supported by classical trajectory calculations, which reveal that the highest-energy harmonics are sourced from one or two cycles of the fundamental pulse depending on the time delay.

Figure 4 shows the cutoff energy and caustic intensity as a function of time delay for the short 2ω pulse scheme used in Fig. 1(a). The caustic intensity is the peak intensity in the cutoff harmonics and the cutoff energy is extracted for each time delay by sight. We note that there are two cutoff energies as using a two-color field results in HHG spectra with double plateaus [30]. These two plateaus correspond to trajectories launched at a combined peak/peak or peak/trough of the two color field. As a result, the caustic intensity and cutoff energies oscillate with half the period of the 400-nm pulse: The half-(800nm)-cycle symmetry of the three-step HHG mechanism is broken by the inclusion of the 400 nm pulse.

The two cutoff energies are anti-correlated— an extension of the higher-energy cutoff reduces the cut-off energy of the first plateau. At certain time delays the cutoff energies overlap, and we observe a single plateau: for these time delays, classical trajectory calculations reveal that there are trajectories of approximately equal return energy launched on multiple field peaks. The peak caustic intensity occurs when the cutoff of the first plateau is at a minimum. The intensity along the arms of the swallowtail in Fig. 1 then decreases as the pulse arrangement yields higher-energy trajectories at the expense of a lower ionization probability.

Extending the second plateau to higher energy comes at the expense of a reduction of yield in the second plateau. As the cutoff energy increases, the caustic at the first cutoff becomes more intense, dominating the spectrum. The peak caustic intensity occurs when the...
second cutoff energy is at its highest. This occurs at a time delay of 0.17 fs, not zero delay as might be expected naively. To elucidate this further, we perform calculations for different primary wavelengths, and find that the offset from zero-delay is a constant phase difference of approximately $\pi/7$ (Tab. 1).

This offset, approximately 7% of the field period, is the proportion of the pulse peak where the electric field can be considered to be quasistatic (over 97% of its peak strength). Tunnel ionization is most likely in this quasistatic window. For this optimal phase offset the peak of the $2\omega$ pulse arrives just after that of the fundamental pulse, broadening the central peak and enhancing ionization. The green shaded regions of Fig. 3 highlight the trajectories which are launched by such broadened peak. It can be seen that these trajectories yield lower-energy harmonics than those which are launched in the unshaded regions. Thus the most likely ionization event yields the spectral caustic, while at the same time delay, much higher-energy trajectories are launched but with vanishingly small probability (Fig. 5). For the two time delays on either side of zero delay which yield the most intense caustics, the yield at the first plateau is three orders of magnitude larger than the yield in the second.

The main caustic, (time delay $\approx 0.17\text{fs}$) has nearly twice the intensity of the second (time delay $\approx 0.5\text{fs}$). This is because the field strength at the central peak is higher than in the penultimate trough. Both of these caustics arise when a peak (trough) of the $2\omega$ pulse arrives just after a peak (trough) of the $\omega$ pulse. For a time delay one half cycle of the $2\omega$ pulse sooner or later, the positions of the peaks and troughs of the 400-nm pulse relative to the 800-nm pulse are reversed. A trough of the $2\omega$ pulse occurring after the peak of the 800-nm pulse results in a shorter, flatter fundamental peak decreasing the ionization probability and therefore the harmonic yield. Thus periodic reduction in cumulative yield, seen as the blue horizontal bands in Fig. 1(a) and more explicitly in Fig. 5, occur when a trough of the 400-nm pulse coincides with the peak of the 800-nm pulse.

V. CONCLUSION

The continued improvement of both large-scale and table-top laser technology has created increased flexibility to shape light pulses, controlling both their spectral and temporal properties [31]. Although an aligned $\omega - 2\omega$ scheme is by no means the most sophisticated or complex arrangement, it nonetheless provides a tractable insight into the strong-field dynamics of atomic electrons. In this paper we have assessed the behavior of a neon atom exposed to such a combination of pulses. While it was previously well known that employing the second harmonic field could substantially increase both the harmonic yield and cut-off, we have seen that using a short, few-cycle $2\omega$ pulse can elicit more interesting behaviours. In particular, a short $2\omega$ pulse can stimulate different interference structures in the harmonic spectrum—leading to spectral caustics and continua or comb-like fringes depending on the precise shape of the pulse.

Also, using both the RMT method and a classical trajectory model we are able to assess the mechanisms by which the HHG yield and cut-off are affected. Namely, a broadening of the fundamental peak leads to increased tunnel ionization and thereby increased HHG yield, while a simultaneous narrowing of the previous trough increases the electron excursion time, increasing the collision velocity and hence the cut-off energy.

With the enhanced ability to shape light pulses in experiment, it will become increasingly important to understand in detail the response of atoms and molecules to more complex arrangements of laser pulses. To this end, it will be interesting to use the capabilities of the RMT method to identify schemes whereby the signatures of multielectron correlation and atomic structure can be extracted from high-order-harmonic spectra.
