- multivalency;
- nanochemistry;
- self-assembly

High-affinity binding between nanoscale objects is an essential prerequisite for “bottom-up” fabrication.1 In recent years, interest has focused on the use of dendritic macromolecules as supramolecular nanoscale building blocks.2 The branched superstructure of dendrons and dendrimers offers specific advantages, for example, enhancement of weak binding by using multivalent arrays of recognition units on the dendritic surface. This multivalency principle, in which organized arrays amplify the strength of a weak binding process, such as the binding of saccharides to proteins on cell surfaces, is now well established.3

DNA constitutes a particularly interesting target for nanotechnological exploitation.4 High-affinity binding of DNA is useful for protecting DNA and ultimately for delivering genetic information into cells.5 Noncovalent interactions between dendritic macromolecules and DNA are, therefore, of considerable current interest.6 Polyamidoamine (PAMAM) dendrimers were the first systems to be investigated,7 while dendritic poly(L-lysine)8 and poly(propylene imine)9 have also been studied recently. In general, higher-generation, or structurally fractured, systems are usually more effective...
for DNA binding and delivery. In an important recent study, however, Diederich and co-workers reported low-molecular-mass dendrons designed to self-assemble with DNA, which were capable of gene therapy.\textsuperscript{10}

The interaction between a single protonated amine and the phosphate backbone of DNA is relatively weak and must compete with salt binding under biological conditions. Biology therefore uses tetraamines, such as spermine (Scheme 1!?!), to achieve DNA binding.\textsuperscript{11} Synthetic spermine derivatives are also widely used for applications in DNA binding and delivery.\textsuperscript{12} However, although spermine is better than an isolated amine for binding DNA, the interaction is still relatively weak and the complex is mobile. Consequently, spermine struggles to compete with DNA-bound inorganic cations.\textsuperscript{13}

We became interested in optimizing DNA binding and developing low-molecular-mass dendrons with very high affinities for DNA—such systems would be particularly useful for DNA encapsulation and protection.\textsuperscript{14} We therefore decided to develop dendrons that express multivalent spermine arrays on their surfaces. Some previously reported multivalent spermine arrays comprised multiple spermine groups grafted onto dextran polymers;\textsuperscript{15} however, we wanted to develop multivalent systems with well-defined molecular structures. Such monodisperse systems enable an understanding of structure–activity relationships and, in addition, have a greater chance of being licensed for therapeutic applications in the longer term. Herein, we report on multivalent dendritic spermine constructs with extremely high, salt-independent binding affinities for DNA.
We used a divergent synthetic approach to construct target compounds $G_1$ and $G_2$ (Scheme 1, details of the synthesis can be found in the Supporting Information). Newkome-type branching was used as the dendritic scaffold, as such structures are readily synthesized and should be biocompatible. After dendron synthesis, the surface was functionalized with spermine groups which had been appropriately protected by using the methodology of Blagbrough and Geall. Deprotection of the spermine groups with HCl gas then yielded target compounds $G_1$ and $G_2$. Model compound $G_0$ was constructed by using a similar approach (Scheme 1). All synthetic steps were high yielding and all target compounds and intermediates were fully characterized with standard methods (see the Supporting Information).

Initially, the binding of the spermine derivatives to DNA was studied by using an ethidium bromide displacement assay. This method is commonly used to study the binding of polyammonium compounds to DNA. The displacement of ethidium bromide from its complex with DNA can be monitored because it has enhanced fluorescence when intercalated. This is a powerful comparative method, although the resulting data reflect a competition assay, rather than an absolute binding strength, and furthermore give no information about binding stoichiometry.

Fluorescence titrations were performed in buffered water at pH 7.2 using $G_0$, $G_1$, $G_2$, and spermine itself. The resultant titration profiles are shown in Figure 1. At this physiologically relevant pH value, the spermine groups are largely protonated whilst the DNA is largely deprotonated, so electrostatic interactions are maximized.

![Figure 1](image.png)

**Figure 1.** Fluorescence titration profiles for the addition of spermine, $G_0$, $G_1$, or $G_2$ to a solution of calf thymus DNA and ethidium bromide in buffered water (pH 7.2) in the presence of 150 mM NaCl.

The data can be presented in terms of $C_{50}$ and $CE_{50}$ values (Table 1). $C_{50}$ values report the concentration of polyamine causing a 50% decrease in fluorescence intensity. $CE_{50}$ values represent the “charge excess” required to achieve the same 50% reduction in fluorescence—the very best DNA binders should have $CE_{50}$ values below 1.0. Spermine binds to DNA with moderate strength under low-salt (9.4 mM NaCl) conditions ($C_{50}=1.33 \, \mu M$, $CE_{50}=5.3$), but a very large charge excess would have been required at physiological salt concentrations (150 mM NaCl) in order to achieve...
50 % quenching of ethidium bromide fluorescence ($C_{50}=390 \mu M$, $CE_{50}=1560$). These results were in good agreement with literature data.\textsuperscript{19a} Compound G0 showed similar, if slightly weaker, DNA binding. This was expected, as one of the primary amines of spermine has been converted into an amide, which is incapable of protonation, and G0 should therefore exhibit weaker electrostatic interactions with polyanionic DNA.

| Table 1. Results for spermine, G0, G1, and G2 from an ethidium bromide displacement assay.\textsuperscript{[a]} |
| --- | --- | --- | --- | --- |
| Compound | [NaCl] [mM] | Nominal charge | $C_{50}$ [μM] | $CE_{50}$ |
| spermine | 9.4 | 4+ | 1.33 | 5.3 |
| G0 | 9.4 | 3+ | 20 | 60 |
| G1 | 9.4 | 9+ | 0.076 | 0.68 |
| G2 | 9.4 | 27+ | 0.030 | 0.81 |
| spermine | 150 | 4+ | 390 | 1560 |
| G0 | 150 | 3+ | 220 | 660 |
| G1 | 150 | 9+ | 0.300 | 2.70 |
| G2 | 150 | 27+ | 0.028 | 0.76 |

The dendritic systems G1 and G2 showed significantly enhanced DNA binding. Under low-salt conditions, G1 effectively displaced ethidium bromide from DNA ($C_{50}=76$ nM, $CE_{50}=0.68$). Notably, the affinity for DNA is considerably more than three times higher than that of G0. This indicates that the organization of three spermine units on the dendritic framework enables DNA-binding activity that is more than the simple sum of its individual parts—the multivalency principle in operation. Compound G1 is somewhat affected by the increase in salt concentration but still shows reasonable binding under these conditions ($C_{50}=300$ nM, $CE_{50}=2.70$).
Compound G2 shows a similar binding affinity to G1 under low-salt conditions ($C_{50}=30$ nM, $CE_{50}=0.81$) but demonstrates its power at physiological salt concentrations, where the binding remains just as strong ($C_{50}=28$ nM, $CE_{50}=0.76$). The binding is therefore salt independent—a proactive dendritic effect. The multivalent system can therefore compete with Na$^+$ ions for binding sites on the surface of the DNA helix. Indeed, compound G2 exhibits one of the best binding profiles reported by using this method, thereby proving that the strategy of organizing spermine units into a well-defined multivalent array has considerable power.

Gel electrophoresis was used to confirm the affinities of the dendrons for DNA in a direct binding assay. The dendritic constructs G1 and G2 retarded the electrophoretic mobility of DNA as a consequence of charge neutralization, whilst the spermine and G0 analogues were ineffective (Figure 2). The CE values at which mobility was retarded were in agreement with the results of the ethidium bromide displacement assays.

Figure 2. Gel electrophoresis of plasmid DNA (250 ng per lane). Lane 1: Plasmid DNA. Lane 2: Plasmid DNA + spermine (250 ng). Lane 3: Plasmid DNA + G0 (250 ng). Lane 4: Plasmid DNA + G1 (250 ng). Lane 5: Plasmid DNA + G2 (250 ng).

Finally, transmission electron microscopy (TEM) was used to image the complexes (Figure 3). The addition of spermine at CE=1.8 to plasmid DNA in buffered water (pH 7.1, [NaCl]=9.4 mM) prior to deposition on a carbon-coated copper grid gave rise to large unsymmetrical aggregates approximately 250 nm in diameter (Figure 3 A). Compound G0, however, led to little or no compaction of DNA under the same conditions. On the other hand, use of G1 or G2 (CE=2.7) gave rise to well-defined, approximately spherical nanoscale complexes (G1: approximately 100 nm in diameter; G2: approximately 400 nm in diameter) with no free plasmid being detected (Figures 3 B, C). The size range of the aggregates formed was relatively large. Nonetheless, these observations indicate that compounds G1 and G2 efficiently bind DNA and condense it into approximately spherical complexes.
Figure 3. TEM images of DNA in the presence of A) spermine (CE=1.8), B) G1 (CE=2.7), or C) G2 (CE=2.7). Samples were deposited from buffered water (pH 7.1).

In summary, we have reported novel dendrons that bind DNA with remarkably high affinities. Notably, G2 showed salt-independent DNA binding and it was a factor of ten more effective than the G1 analogue under high-salt conditions, whilst G1 was, in turn, significantly more effective than the G0 analogue. It can be concluded that the expression of multiple spermine units, nature’s own DNA binder, on the surface of a dendritic scaffold offers a powerful approach for achieving high-affinity DNA binding under physiological conditions. These molecules have potential for further synthetic variation, and in current and future work, we will be investigating the effect of structural modifications on DNA binding and nanoscale assembly, as well as looking at applications of the novel dendritic constructs in gene protection and delivery.

Charge excess is defined as the nominal “number of positive charges” of the polyamine divided by the “number of negative charges” present on the DNA. A molecular weight of 660 g mol⁻¹ per base pair and one negative charge per nucleotide were assumed.
