Walking for Musculoskeletal Pain: Review

ABSTRACT

Objective: To systematically review the evidence examining effects of walking interventions on pain and self-reported function in individuals with chronic musculoskeletal pain.

Data Sources: Six electronic databases (Medline, CINAHL, PsychINFO, PEDro, SportDiscus and the Cochrane Central Register of Controlled Trials) were searched from January 1980 up to March 2014.

Study Selection: Randomized and quasi-randomized controlled trials in adults with chronic low back pain, osteoarthritis or fibromyalgia comparing walking interventions to a non-exercise or non-walking exercise control group.

Data Extraction: Data were independently extracted using a standardized form. Methodological quality was assessed using the United States Preventative Services Task Force (USPSTF) system.

Data Synthesis: Twenty-six studies (2384 participants) were included and suitable data from 17 were pooled for meta-analysis with a random effects model used to calculate between group mean differences and 95% confidence intervals. Data were analyzed according to length of follow-up (short-term: ≤8 weeks post randomization; medium-term: >2 months - 12 months; long-term: > 12 months). Interventions were associated with small to moderate improvements in pain at short (mean difference (MD) -5.31, 95% confidence interval (95% CI) -8.06 to -2.56) and medium-term follow-up (MD -7.92, 95% CI -12.37 to -3.48). Improvements in function were observed at short (MD -6.47, 95% CI -12.00 to -0.95), medium (MD -9.31, 95% CI -14.00 to -4.61) and long-term follow-up (MD -5.22, 95% CI 7.21 to -3.23).
Walking for Musculoskeletal Pain: Review

Conclusions: Evidence of fair methodological quality suggests that walking is associated with significant improvements in outcome compared to control interventions but longer-term effectiveness is uncertain. Using the USPSTF system, walking can be recommended as an effective form of exercise or activity for individuals with chronic musculoskeletal pain but should be supplemented with strategies aimed at maintaining participation. Further work is also required examining effects on important health related outcomes in this population in robustly designed studies.

Key words: Meta-analysis, walking, exercise, chronic musculoskeletal pain.
Walking for Musculoskeletal Pain: Review

Chronic musculoskeletal pain (CMP) is a major cause of morbidity.(1) Given the changing age profile of the population it is probable that its prevalence and associated costs will continue to rise.(1,2) Chronic low back pain (CLBP), osteoarthritis (OA) and fibromyalgia syndrome (FMS) are reported as being among the most common types of musculoskeletal disorder. These conditions may be associated with significant functional limitations.(2) There is also evidence that they can exert a substantial influence on long-term health status and overall quality of life.(1,3)

Current treatment recommendations support various non-pharmacological interventions, including aerobic exercise, in order to reduce pain and maintain or increase functional status.(4-6) However, randomized controlled trials have tended to report only short-term improvements in outcome with relatively small effect sizes.(7,8) This may be due to a number of factors, including heterogeneity of interventions.(9)

Walking may represent an ideal form of aerobic activity, due to its ease of accessibility and relatively low impact. It has a low risk of musculoskeletal injury,(10) and is considered safe to recommend for previously sedentary individuals.(11) Low to moderate intensity walking (described as exercising at a MET value of between 3-4 (12) or a pace that results in an increased respiratory and heart rate, but where the individual can still carry out a conversation) has been shown to lead to improvements in aerobic capacity, body mass index, systolic/diastolic blood pressures, triglyceride, and high density lipoprotein cholesterol levels in healthy sedentary individuals,(13,14) as well as in those with established cardiovascular disease (15) and type 2 diabetes.(16)
Walking for Musculoskeletal Pain: Review

Although it is widely recommended, there is currently limited evidence relating to the effectiveness of walking exercise for management of musculoskeletal disorders.(17)

The aim of this systematic review was to examine the effects of walking interventions on pain and self-reported function in adults with CMP.

METHODS

Data sources, searches and extraction

Comprehensive search strategies were carried out by at least two independent reviewers according to the preferred reporting items for systematic reviews and meta-analyses (PRISMA) recommendations and those of the Cochrane Musculoskeletal Review Group.(18,19) A review protocol was developed 'a priori' using the PICOS framework to define the research question and inclusion criteria. Six electronic databases (Medline, CINAHL, PsychINFO, PEDro, Sport Discus and the Cochrane Central Register of Controlled Trials) were searched for relevant papers published between January 1980 and March 2014 using combinations of key terms which included “walking”, “aerobic exercise”, “musculoskeletal pain”, “low back pain”, “arthritis” and “fibromyalgia” (A full list of the MeSH terms used is included in Supplementary data: Appendix A). Reference lists of included articles and key systematic reviews were also checked by hand.

All randomized or quasi-randomized studies published in full were considered for inclusion. No language restrictions were applied. Studies were required to include
Walking for Musculoskeletal Pain: Review

adults aged 18 years or over, with a diagnosis of CLBP, OA or FMS made according to clinical judgement or accepted diagnostic criteria. (6,20,21)

All land or treadmill based walking interventions were considered for inclusion. Studies were required to include a comparative non-exercise or non-walking exercise control group. Those including any form of assisted walking were excluded. Studies were also excluded if they involved peri-operative or post-operative interventions. Primary outcomes of interest were pain and self-reported function.

At least two reviewers independently examined titles and abstracts of identified studies. Full text copies of potentially eligible studies were assessed to determine whether walking formed at least half of the overall intervention. Final inclusion was determined by consensus between review authors. Data were extracted independently using a standardised form. Disagreements were resolved by consensus and involved a third author if required. Intervention and control group sample size, plus mean and standard deviation (SD) values for pain and function were extracted. Where the SD was not provided it was calculated from the standard error (SE) or 95% confidence intervals (95% CI). Where tabulated results were not presented, an attempt was made to extract data from graphs. All data were cross checked by a second author. For the purposes of comparability, outcomes were converted to a 0-100 scale (with higher scores indicating greater pain or functional limitation).

Assessment of methodological quality and adequacy of exercise interventions

The United States Preventative Services Task Force (USPSTF) system was used to assess methodological quality and form treatment recommendations based on an
Walking for Musculoskeletal Pain: Review

estimate of net benefit and the overall strength of evidence.(22) Internal validity and external validity were rated as “good”, “fair”, or “poor” according to pre-defined criteria specific to the study design.(23) (See supplementary data: Appendix B). Studies rated as “good” met all relevant criteria. Fair studies did not meet all criteria while “poor” studies were judged to contain a serious methodological flaw. Individual studies were given an overall rating, with internal and external validity considered to have equal weighting. Included studies were also screened for statements indicating sources of funding or support. Reviewers were not blinded with regards to study authors, institution, or journal of publication. All final decisions regarding quality assessment and overall recommendations were reached by consensus. Studies were also scrutinized independently to determine if the interventions met American College of Sports Medicine (ACSM) guidelines for the quantity and quality of aerobic exercise in inactive individuals based on frequency, intensity, timing, mode and duration of interventions.(24)

Data synthesis and analysis

The meta-analysis compared mean values for pain and function between walking intervention and control groups. To avoid double counting, where multiple treatment groups were included walking was compared only to minimal intervention controls. Suitable studies were considered to be clinically homogeneous on the basis of similarities in participant demographics and intervention methods. These data were pooled and analyzed using RevMan (v.5.2.8).(25) Statistical heterogeneity was assessed using the $\chi^2$ and $I^2$ test statistics. Where the P value was less than 0.05 or the $I^2$ value greater than 50%, indicating large heterogeneity,(26) a random effects model for inverse variance was used to calculate the mean difference and 95%CI.
Walking for Musculoskeletal Pain: Review

Formal statistical tests were not used to assess publication bias, which was evaluated using visual assessment of funnel plots. Data were analyzed by length of follow-up which was categorized as short (≤8 weeks post randomization), medium (2-12 months) or long-term (>12 months). Sensitivity analyses were carried out excluding studies where walking was combined with a co-intervention.

Nine articles were not included in the meta-analysis for the following reasons: no validated self-reported measure of pain or function (27,28) (one study used a functional scale that contained additional questions related to global health status and these data were therefore not included); unadjusted baseline differences between groups;(29,30) presented median data only;(31,32) change over time only(33) or did not include a measure of variability.(34) One study reported pain as an outcome but did not include these data in the paper.(35)

RESULTS

Description of studies

The electronic database searches revealed a total of 2760 articles after exclusion of duplicates. Thirty seven of these met the inclusion criteria (see Appendix C for a list of excluded studies). Eleven were reports of follow-up data or sub-sample analyses. There were therefore 26 original studies in the review including a total of 2384 participants (Mean: 93) with an average age of 57 years (SD: 15), of whom 77% were female. The complete selection process, including reasons for exclusion is shown in Figure 1.
Walking for Musculoskeletal Pain: Review

Twenty four of the studies were randomized controlled trials. Twelve provided data for OA (27-29,31,36-43), eight for FMS (30,33-35,44-47), five for CLBP (32,48-51) and one included participants with chronic hip, lower back or knee pain.(52) Demographic details and study characteristics are summarized in Table 1 and Table 2.

In the majority of interventions (19/26, 73%) walking was supervised in a hospital clinic, gymnasium or other setting (Table 2). Some studies combined supervised walking with instructions to walk at home;(31,37,40) six were home-based only.(28,30,32,38,43,51) Three used pedometers to assist with step-based walking goals (28,43,51) while three used time-based walking goals.(30,32,38)

Thirteen studies included a walking only intervention group. The remaining combined walking with a co-intervention. The most common of which were educational interventions or alternative forms of exercise (Table 2). A range of controls were used including education; usual care; alternative forms of exercise; a passive intervention (relaxation/massage) and a 6-8 week pre-intervention baseline phase. Mean length of final follow-up was 1.8 months (SD: 0.4) for studies with short term outcomes (≤8 weeks post randomization); 4.9 months (SD: 1.9) for medium-term outcomes (>2-12 months); and 18.4 months (SD: 7.6) for long-term outcomes (>12 months).

Eleven studies included a statement of associated adverse events. These included two falls resulting in distal radial fractures, one fall resulting in a hip fracture, one case of plantar fasciitis and two cases of allergic skin reactions to metal pedometer clips. Two studies including participants with fibromyalgia reported a general increase in reporting of pain and muscle stiffness in the intervention group. One study including participants
Walking for Musculoskeletal Pain: Review

with CLBP reported temporary exacerbations in pain levels in a small number of participants which was attributed to unaccustomed activity levels.

Methodological quality and exercise interventions

Overall, the included evidence was judged to be of at least fair methodological quality (Supplementary data: Appendix B). Six studies met all criteria for internal validity and were rated as good.\(^{(32,33,37,47,48,51)}\) A small number of studies (n=5) contained serious potential sources of methodological bias and were therefore rated as poor.\(^{(27,28,30,31,43)}\) This was as a result of inadequate allocation concealment during randomization,\(^{(28,30)}\) unequal distribution of important confounding variables at baseline not accounted for during analysis,\(^{(27,30)}\) no masking of outcome assessment,\(^{(31)}\) or due to a substantial (>50%) drop-out rate and subsequent post hoc revision of the intervention groups examined.\(^{(29)}\) For external validity most studies were rated as fair, with nine rated as good.\(^{(32,33,36,38,42,43,47,50,51)}\) Studies generally included similar populations in terms of demographics and clinical presentation, as well as interventions that would be routinely available or feasible in clinical practice. Visual assessment of funnel plots indicated that there was no substantial evidence of publication bias. Only one study \(^{(27)}\) did not include a statement indicating sources of funding or support. Ten studies \(^{(35-37,40,41,44-46,49,50)}\) included interventions that met all ACSM criteria.\(^{(24)}\) (Supplementary data: Appendix B) While the majority met minimum criteria for frequency of exercise and length of intervention, eleven either did not provide enough detail regarding exercise intensity, or it was not sufficient to effect any change in fitness. Eleven of the 26 studies \(^{(32,33,36,37,39,40,41,43,47,51,52)}\) reported a measure of participant adherence (Table 2). These included attendance at exercise classes (n=7), self-
Walking for Musculoskeletal Pain: Review

reported completion of home exercise (n=2) or self-reported adherence to wearing a pedometer (n=2).
Meta-analysis

Data from 17 of the included studies were suitable for meta-analysis. Although applying the alternative fixed effects model did not substantially alter any analyses, data are presented here using the more conservative random effects model. Analysis revealed significant differences in favour of walking interventions in terms of reduced pain at short (mean difference (MD) -5.31, 95% confidence interval (95% CI) -8.06 to -2.56) and medium-term follow-up (MD -7.92, 95% CI -12.37 to -3.48). No effect on pain was observed for long-term data (MD -2.22, 95% CI -6.03 to 1.59) (Figure 2). For self-reported function, improvements were found at short-term (MD -6.47, 95% CI -12.00 to -0.95), medium (MD -9.31, 95% CI -14.00 to -4.61) and long-term follow-up (MD -5.22, 95% CI -7.21 to -3.23) (Figure 3). Sensitivity analyses excluding studies which combined walking with a co-intervention did not alter overall results.

DISCUSSION

Overall findings indicated that walking interventions were associated with significant improvements in both pain and self-reported function in individuals with CMP. While effects appeared to be maintained beyond the immediate post-intervention period, only differences in function were observed at long-term follow-up. This was based primarily on data derived from interventions lasting for between six and 12 months. It is therefore unlikely that improvements in outcome would be maintained following the shorter intervention periods included in the majority of other interventions. This is supported by additional sub-sample data from one included study which indicated that
Walking for Musculoskeletal Pain: Review

significant improvements in outcome following an eight week intervention were absent at 12 months.(53)

While it has been suggested that supervised interventions may be required to maintain adherence with exercise,(7) other techniques, including those encouraging self-management, may be of benefit.(54) Walking did appear to have a slightly greater effect on function than pain outcomes. Inclusion of educational and behavioral components alongside walking in many studies may have contributed to this apparent effect; lending support to treatment approaches which place greater emphasis on improving function despite continued pain.(55) These interventions are often based on psychological theories such as operant conditioning which use positive reinforcement to reduce negative pain behaviors; for example through graded activity or pacing.(56) The underlying mechanisms contributing to these effects are uncertain but could be related to reduced fear of movement or increased self-efficacy.(55) Although co-interventions varied, there were commonalities: including that they frequently consisted of hospital or clinic-based group discussions (supplemented with written information), with condition-specific and general information on pain management strategies and advice on maintaining exercise. Some studies included additional strategies including goal setting and self-monitoring. Use of self-monitoring techniques including pedometer feedback represents a potentially useful method to increase walking in individuals with CMP disorders.(43,51) However, these methods have not been widely tested. This is reflected in the fact that only three of the included studies used pedometers. A recent study examining a remote, web-delivered pedometer intervention (excluded from this review as it compared two forms of walking) found no
long-term effects on functional outcomes. Further work is required examining pedometer interventions in this population which are delivered within a clinical setting.

To our knowledge, this is one of the first systematic reviews to examine the effects of walking in a range of CMP disorders. A previous review (58) examining walking for LBP (both acute and chronic) found limited evidence to support its use as a primary intervention. Roddy and co-authors (59) found aerobic walking to be equally as effective as strengthening at reducing pain and disability in knee OA. Other reviews examining the effects of general aerobic exercise interventions in CMP (7,8,60,61) have provided conflicting results, with limited evidence to support the use of any one type or intensity of exercise. While aerobic exercise may lead to improved overall well-being and physical function it is often associated with little or no difference in pain. In contrast, others have shown slight to moderate intensity aerobic exercise to be effective at reducing pain; however this latter review did not look directly at effects on functional data.

**Study strengths and limitations**

This review has a number of strengths, including an extensive search of the available evidence, rather than limiting inclusion to studies selected on the basis of experimental design. We also included studies which involved only walking-based interventions, allowing for examination of a more homogenous intervention type than has previously been examined. Studies were considered to be similar on the basis of clinical characteristics and intervention methods. The majority involved supervised treadmill or land-based interventions (commonly within a hospital or clinic gymnasium setting), of between six to eight weeks duration. A number of these studies included more
Walking for Musculoskeletal Pain: Review

independent home-based walking as an additional exercise element and we were therefore unable to determine the influence of treatment setting on outcomes.

We were unable to use sensitivity analysis to examine studies separately on the basis of quality as only one study included in the meta-analysis contained a potential serious methodological flaw which could have compromised its validity. Use of the USPSTF system allowed a qualitative assessment of the overall evidence to be made, and the findings and conclusions were broadly similar between this assessment method and the results of the meta-analysis.

There are some limitations which should be taken into account when considering these findings. A small number of studies had methodological limitations, including inadequate allocation concealment in randomized controlled trials or lack of an appropriate method for dealing with missing data. In six studies there was insufficient information on masking of outcome assessments and with additional information it is possible that some studies rated as “fair” may have been rated as “poor” which would influence the recommendation made on the basis of the evidence included in the review. Many studies lacked sufficient detail to assess adequacy of the exercise interventions. The overall effects of the interventions may also have been attenuated by the small number of non-intervention control groups. Furthermore, few studies reported whether there were any associated adverse events. Even among the more supervised interventions, there was limited detail regarding participant adherence. Further research is required examining interventions which use objective measurement of overall physical activity as both an important outcome and a method for increasing motivation and use of self-monitoring. Objective monitors are more accurate than
Walking for Musculoskeletal Pain: Review

subjective assessment methods, due to recall and social-desirability biases of subjective reports (63). Objective monitors such as pedometers can give immediate feedback on performance (prompting adherence), however, one limitation is that they require the user to remember to put them on. Other solutions, such as wrist worn, waterproof devices, that don’t need to be removed for sleep or water based activities may offer a solution, but may not provide the same quality of visual feedback that a pedometer does. Such issues should be considered in the design of future research.

Conclusions

Meta-analysis of data from studies of at least fair methodological quality demonstrated that walking may lead to improvements in outcome, comparable to other forms of exercise. Using the USPSTF system to summarize the existing evidence, walking-based exercise can be recommended for individuals with CMP. However, robustly designed research is required examining longer-term maintenance of walking programs and their effects on important health related outcomes in this population.

AUTHOR CONTRIBUTIONS

All authors contributed to the conception and design of this review. SOC, BR, CB and SMcD were responsible for conducting the search strategies and extracting study data. SOC, MT, GDB, JB and SMcD were responsible for assessment of study quality and rating the overall strength of evidence. SOC drafted the manuscript and all authors contributed to and approved the finalised version.

Using the following guideline criteria, internal and external validity of individual studies were judged as “good” “fair” or “poor” based on the following guideline criteria:

For internal validity: (1) Initial assembly of comparable groups: For RCTs: Adequate randomization including concealment and whether potential confounders were distributed equally among groups. (2) Maintenance of comparable groups (includes attrition, crossovers, adherence, and contamination). (3) Important differential loss to follow-up or overall high loss to follow-up. (4) Measurements: equal, reliable, and valid (includes masking of outcome assessment). (5) Clear definition of interventions. (6) All important outcomes considered. (7) Analysis: Intention-to-treat analysis used for RCTs.

For external validity: (1) Biologic plausibility. (2) Similarities of the populations studied and primary care patients (in terms of risk factor profile, demographics, ethnicity, gender, clinical presentation, and similar factors). (3) Similarities of the test or intervention studied to those that would be routinely available or feasible in typical practice. (4) Clinical or social
environmental circumstances in the studies that could modify the results from those expected in a primary care setting.

American College of Sports Medicine (ACSM) criteria for assessment of the adequacy of exercise interventions in individual studies: (1) Frequency of exercise of at least three days per week or twice a week for deconditioned individuals. (2) Intensity of exercise sufficient to achieve equal to or greater than 40% of heart rate reserve (min-max: 40-85%) or 64% of predicted maximum heart rate (min-max: 64-94%). (3) Sessions of at least 20 minutes duration (min-max: 20-60 minutes), either as continuous exercise or spread intermittently throughout the day in blocks of 10 minutes or more. (4) A mode of aerobic exercise involving major muscle groups in rhythmic activities. (5) Intervention should last for a minimum of six weeks.
