Understanding the transport properties of charged particle beams is not only important from a fundamental point of view, but also due to its relevance in a variety of applications. A theoretical model is established in this article, to model the interaction of a tenuous positively charged ion beam with an ultradense quantum electron-ion plasma, by employing a rigorous relativistic quantum-hydrodynamic (fluid plasma) electrostatic model proposed in [M. McKerr et al, Phys. Rev. E, 90, 033112 (2014)]. A nonlinear analysis is carried out to elucidate the propagation characteristics and the existence conditions of large amplitude electrostatic solitary waves propagating in the plasma in the presence of the beam. Anticipating stationary profile excitations, a pseudo-mechanical energy balance formalism is adopted to reduce the fluid evolution equation to an ordinary differential equation. Exact solutions are thus obtained numerically, predicting localized excitations (pulses) for all of the plasma state variables, in response to an electrostatic potential disturbance. An ambipolar electric field form is also obtained. Thorough analysis of the reality conditions for all variables is undertaken, in order to determine the range of allowed values for the solitonic pulse speed and how it varies as a function of the beam characteristics (beam velocity, density).

I. INTRODUCTION

Quantum plasmas are ubiquitous in astrophysical environments, e.g. in planetary interiors, in white dwarfs, magnetars and pulsars [1, 2] and are relevant in applications, e.g. related with quantum wells [3], plasmonics [4], spintronics [5] and ultra-cold plasmas [6]. Quantum plasma effects are also of relevance in solids, in particular metals, for which the conduction electrons can be viewed as a mobile plasma neutralized by background ions [7]. Quantum degeneracy effects start playing a significant role when the de Broglie length \( \lambda_B \), which represents the spatial extension of the particle’s wavefunction, is larger than the average inter-particle distance. Thus, the particle cannot be considered as pointlike any more, as in classical plasma, and quantum interference of overlapping particles wave functions needs to be taken into account [8]. When the Fermi temperature exceeds the thermal temperature, the equilibrium distribution function changes from Maxwell - Boltzmann to a Fermi-Dirac distribution [9, 10]. Quantum effects are manifested in dense plasma in various ways, e.g. quantum statistical pressure may be dominant (exceeding the thermal pressure), quantum wave diffraction or tunneling (modeled via a Bohm potential) and adopting a quantum exchange and correlation potential (due to spin effects) may be necessary in the modeling [11–13].

Ion beams are relevant in various real applications of plasmas, including heavy ion inertial fusion [14–16], intense laser-produced proton beams for laser-based fast ignition (inertial confinement fusion, ICF) schemes [17–20], semiconductor lasers [21–23] and electron cooling of ion beams [24, 25]. Nonlinear electrostatic (ES) localized modes (nonlinear waves) occur widely in plasmas [26, 27]; the impact of ion beam injection in a plasma has been studied theoretically [28] and also numerically, e.g. via particle-in-cell (PIC) simulations [29–33].

Relativistic effects become relevant when either the bulk (fluid) velocity of a plasma fluid component is comparable in order of magnitude to the velocity of light, or when the average kinetic energy of the charged particles is greater than the electron rest energy (e.g. the Fermi energy of plasma \( E_F \geq m_e c^2 \)) [34]. This may happen under the influence of an ultrastrong electromagnetic field, e.g. a laser beam [35, 36]. In the framework of interaction of intense laser pulses with underdense plasma, relativistic localized solitary pulses, commonly regarded as self-trapped localized structures, have been detected experimentally [37–39] and have also been modeled numerically, via PIC simulations [40, 41]. A wide variety

of nonlinear mechanisms may affect the formation and propagation of relativistic solitons, such as finite particle inertia, relativistic particle mass variation, ponderomotive forces, etc. [42–44].

A comprehensive model was elaborated in Ref. [45], within the electrostatic approximation, taking into account (quantum) electron degeneracy in combination with a relativistic formulation of fluid dynamics. Subsequent work based on that model has revealed the existence of an acoustic and a Langmuir-like mode(s) [46], in analogy to the classical version of the problem [47], whose characteristics take into account relativistic and quantum effects (becoming important at high densities), as expected. When a tenuous ion beam penetrates the plasma [54], a second low frequency acoustic mode arises; the energy excess due to the beam may then destabilize both acoustic modes, and a beam-plasma instability occurs [54]. For a tenuous beam, the instability growth rate is weak and fails to destabilize electrostatic vibrations, as it operates in a narrow wave number window.

In this article, we investigate, from first principles, the dynamical characteristics of localized modes (solitary waves) propagating in an ultradense electron-ion plasma permeated by a secondary ion beam. Building upon the formalism introduced in Ref. [45], here extended to accommodate the dynamics of the ion beam, a multifluid relativistic model for electrostatic plasma excitations is laid out in the next Section and its validity and physical limitations are discussed. Nonlinear analysis based on a (Sagdeev type [49, 50]) pseudopotential method is carried out in Section III, leading to a set of explicit expressions for the state variables in terms of the electrostatic potential (disturbance). The existence of localized forms (pulses) is possible in certain regions in parameter space, which are explored in Section IV. A parametric analysis follows, in Section V, elucidating the dependence of electrostatic pulse characteristics on the beam properties and other intrinsic plasma parameters. Our findings are finally summarized in the concluding Section VI.

II. A MULTIFLUID RELATIVISTIC PLASMA MODEL

We consider a three-component plasma consisting of a dominant ion population (mass $m_i$, positive charge $q_i = +Ze$), a secondary ion species, representing a tenuous beam (mass $m_b$, charge $q_b = +Z_be$) and electrons (mass $m_e$, charge $-e$); $e$ denotes the elementary (absolute) charge, as usual. We consider the spatial variation of the plasma (including the ion beam) to be in the longitudinal direction, so the plasma dynamics can be described by a one-dimensional (1D) geometry for simplicity. Our study relies on a multifluid approach, to be introduced in the following paragraph. We assume from the outset that magnetic field generation may be neglected, within the electrostatic approximation, implying that the total current is negligible (nearly quiescent plasma); clearly, a very weak beam current is implied by this model, as the electrostatic approximation breaks down for strongly relativistic beam flows. Our description follows closely the electrostatic relativistic model proposed in Refs. [45, 46], thus extending the analytical framework proposed therein to take into account the ion beam.

The dominant (positive) ion population will be treated as a cold (classical) fluid, for simplicity; a plausible assumption, given their high mass (compared to the electrons). The continuity and momentum equations of motion for the ion fluid respectively read:

$$\frac{\partial (\gamma_in_i)}{\partial t} + \frac{\partial (\gamma_in_iku_i)}{\partial x} = 0,$$

$$\frac{\partial (\gamma_in_iu_i)}{\partial t} + u_i\frac{\partial (\gamma_in_iu_i)}{\partial x} = -\frac{eZe_i}{m_i}\frac{\partial \phi}{\partial x},$$

where $\epsilon$ is the electron charge, $Z_i$ is the ion charge state, $m_i$ is the ion mass, $n_i$ is the ion fluid density and $u_i$ is the ion fluid speed. One recognizes the electrostatic force $q_iE$ in the right-hand side (RHS) of the momentum equation, where $E = -\partial \phi/\partial x$ is the electric field deriving from an electrostatic potential function $\phi$.

The electron fluid equations read [45]:

$$\frac{\partial (\gamma_en_e)}{\partial t} + \frac{\partial (\gamma_en_eu_e)}{\partial x} = 0,$$

$$\sqrt{1 + \xi^2}\left[\frac{\partial (\gamma_en_eu_e)}{\partial t} + u_e\frac{\partial (\gamma_en_eu_e)}{\partial x}\right] = \frac{\epsilon}{m_e}\frac{\partial \phi}{\partial x} - \frac{\gamma_e}{n_em_e}\left(\frac{\partial P_e}{\partial x} + \frac{u_e}{c^2}\frac{\partial P_e}{\partial t}\right),$$

where $m_e$ is the rest mass of the electron, $n_e$ is the electron fluid (number) density and $u_e$ is the electron fluid speed. In the latter equation, the parameter $\xi = pFe/m_ec = hne/(4m_ec)$ is related to the (high) electron density (note that the classical limit is recovered for $\hbar \to 0$).

In ultrahigh density conditions, electron degeneracy effects become significant, and in fact far exceed the thermal pressure and, in very high densities, quantum pressure (expressed via a Bohm term [10]) too. The electrons then obey a Fermi-Dirac distribution, associated with an appropriate equation of state, which is incorporated in the model via the effective degeneracy pressure term in the highly relativistic limit, i.e. the last term in Eq. (4). Within our model, the quantum relativistic pressure term derives from the (1D) equation of state [45, 51]:

$$P_e = \frac{2m_e^2c^3}{\hbar} \left[\xi (1 + \xi^2)^{1/2} - \sinh^{-1} \xi\right].$$

One also distinguishes in the RHS of (4) the electrostatic force term, which relates the momentum equation to the electrostatic potential $\phi$. 

The equations of motion for the ion beam read:

\[
\frac{\partial (\gamma_b n_b)}{\partial t} + \frac{\partial}{\partial x} (\gamma_b n_b u_b) = 0, \\
\frac{\partial (\gamma_b u_b)}{\partial t} + u_b \frac{\partial (\gamma_b u_b)}{\partial x} = -\frac{e Z_b \delta \phi}{m_b \partial x},
\]

where \(m_b\) is the beam ion mass, \(n_b\) is the beam ion fluid density and \(u_b\) is the beam ion fluid speed. The relativistic factor \(\gamma_j = 1/\sqrt{1 - u_j^2/c^2}\) (for \(j = i, e, b\)) appears in the fluid-dynamical equations, as a result of Lorentz transformations and resulting relations among different state variables between inertial frames.

The system is closed by Poisson’s equation:

\[
\frac{\partial^2 \phi}{\partial x^2} = \frac{e}{\epsilon_0} (\gamma_e n_e - \gamma_i Z_i n_i - \gamma_b Z_b n_b).
\]  

In the above relations, \(c\) is the speed of light in vacuo, \(h\) is Planck’s constant, \(\epsilon_0\) is the permittivity of free space and \(e\) is the fundamental unit of electric charge. The quasineutrality condition, assumed to hold at equilibrium (only), can be written as follows: \(n_{e0} - Z_i n_{i0} - Z_b \gamma_b n_{b0} = 0\), where \(n_{e0}, n_{i0}\) and \(n_{b0}\) are the unperturbed densities of the electron, ion and beam ion population(s), respectively.

A. Rescaled (dimensionless) fluid-dynamical model

The fluid model can be cast in a dimensionless form, by adopting a set of characteristic scales:

\[
t \rightarrow \omega_p t, \quad x \rightarrow \omega_p x/c_s, \\
n_j \rightarrow n_j/n_{j0}, \quad u_j \rightarrow u_j/c_s, \\
\text{and} \quad \phi \rightarrow e\phi/2E_{Fc},
\]

for \(j = i, e, b\), where \(\omega_p = \sqrt{Ze^2/n_{e0}/\epsilon_0 m_i}\) is the plasma frequency (in a beam-free e-i plasma). Note that the potential scale \((2E_{Fc}/\phi)\) and the characteristic speed scale \(c_s = \sqrt{2Ze\epsilon_p/m_i}\) are determined as functions of the non relativistic electron Fermi energy \(E_{Fc} = p_{Fe}^2/2m_e\) (and momentum \(p_{Fe} = \hbar n_{e0}/4\)), which in turn prescribes the length scale as \(c_s/\omega_p\).

The fluid equations take the form:

\[
\frac{\partial (\gamma_j n_j)}{\partial t} + \frac{\partial}{\partial x} (\gamma_j n_j u_j) = 0, \\
\frac{\partial (\gamma_j u_j)}{\partial t} + u_j \frac{\partial (\gamma_j u_j)}{\partial x} = -\frac{e Z_j \delta \phi}{m_j \partial x},
\]

where \(H = \sqrt{1 + \xi^2}\) represents the enthalpy of the system [45], where \(\xi = \mu_e \Xi_2\); the relativistic factor is redefined as \(\gamma_j = 1/\sqrt{1 - \alpha u_j^2}\), where \(\alpha = \xi^2/\mu_e \Xi_2^2\).

We have also introduced the ion-to-electron charge ratio \(\beta = Z_i n_{i0}/n_{e0}\), the beam-to-electron charge density ratio \(\delta = Z_b n_{b0}/n_{e0}\), the electron-to-ion mass ratio \(\mu_e = m_e/m_i\) (\(\sim 1/1836 \approx 0.0005 \ll 1\)) and the mass ratio \(\mu_b = m_b/m_i\). Note that overall charge neutrality is assumed at equilibrium (imposing \(\beta = 1 - \gamma_b(\delta)\)).

Small-amplitude (harmonic wave) solutions are straightforward to obtain upon linearizing the model equations (10)-(16) above. The linear aspects of the beam-plasma system dynamics resulting from this framework have been analyzed in detail in Ref. [54] and need’t be repeated here. Actually, two low-frequency acoustic modes exist, propagating at different phase speeds (associated with the two ionic components), in addition to an electron plasma (Langmuir-type) high-frequency mode [46], whose characteristics reflect the relativistic invariance of the model and also incorporate quantum degeneracy effects (that become important at high densities), just as intuitively anticipated. In the presence of the ion beam [54], the surplus energy destabilizes both low-frequency modes [54], though the associated growth rate is weak for a tenuous beam and operates in a narrow wavenumber window.

As a representative “textbook” situation, we shall henceforth consider a hydrogen plasma \((Z_i = 1)\) and a tenuous beam, i.e. implicitly assuming \(\delta \ll 1\) and \(\mu_b \sim 1\) throughout.

III. NONLINEAR ANALYSIS

Let us consider a localized perturbation, in the form of a solitary wave propagating with (dimensionless) speed
Here, \( M = U_{sol}/c_s \), where \( c_s \) here denotes the pseudo-sound speed, which was defined in the previous Section as \( c_s = \sqrt{2Z_iE_{Fe}/m_i} \). We have adopted here an analogy with the so called “Mach number” in electrostatic soliton theory in classical plasmas \([50]\), a terminology which in turn reflects an analogy with real sound (acoustic) waves propagating in air. We pass from the laboratory frame to the moving reference frame by assuming that all quantities are functions of a single variable \( X = x - Mt \), viz.

\[
\frac{\partial}{\partial t} = -M \frac{\partial}{\partial x}, \quad \frac{\partial}{\partial x} = \frac{\partial}{\partial X}.
\]  

(17)

Combining with the system of equations (10)-(16), we obtain the following system of ordinary differential equations (ODEs):

\[
-M(\gamma_i n_i) + (\gamma_i n_i u_i)' = 0,
-M(\gamma_e n_e) + (\gamma_e n_e u_e)' = 0,
-M(\gamma_b n_b) + (\gamma_b n_b u_b)' = 0,
-M(\gamma_i n_i)' + u_i(\gamma_i n_i) + \phi' = 0,
-H(M - u_e)(\gamma_e u_e)' + \frac{\gamma_e n_e}{H\mu_e}(1 - \alpha M u_e)u_e' - \frac{1}{\mu_e} \phi' = 0,
-M(\gamma_b n_b)' + u_b(\gamma_b n_b) + \frac{1}{\mu_b} \phi' = 0,
\phi'' = \gamma_e n_e - \beta \gamma_i n_i - \gamma_b n_b.
\]

(18)

Assuming vanishing boundary conditions for all of the state variables (except the ion beam, which satisfies \( \lim_{X \to \pm \infty} u_b = V_{b0} \)), we have manipulated the latter equations into a set of analytical expressions for the ion, beam-ion and electron fluid density and speed variables, as functions of the electrostatic potential. This was a delicate task, due to the perplex structure of the above equations (in comparison e.g. with classical models \([49, 50]\)). The procedure is described in full detail in the Appendix, for reference, yet unnecessary details are omitted below.

After some tedious but straightforward algebra, we obtain an ODE in the form:

\[
\frac{1}{2} \left( \frac{d\phi}{dX} \right)^2 + S(\phi) = 0.
\]

(19)

Here, \( S \) is a nonlinear function given by

\[
S(\phi) = (1 - \gamma_{b0}\delta)S_i(\phi) + \delta[S_{b1}(\phi) - S_{b0}] - [S_{e1}(\phi) - S_{e0}],
\]

(20)

where

\[
S_i(\phi) = M u_i \gamma_i,
S_{b1}(\phi) = \mu_e \gamma_{b0} u_b \gamma_b \left( M - V_{b0} \right),
S_{e1}(\phi) = \left[ \gamma_e n_e \left( \phi + \frac{H_0}{\xi_0} \right) - \frac{1}{2\xi_0} \left( \sin^{-1} (\xi_0 n_e) + \xi_0 n_e H \right) \right],
S_{b0} = \mu_e \gamma_{b0} V_{b0} \left( M - V_{b0} \right),
S_{e0} = \frac{H_0}{\xi_0} - \frac{1}{2\xi_0} \left( \sin^{-1} (\xi_0) + \xi_0 H \right).
\]

(21)

It is easy to identify the contributions of the three plasma components to the latter expression. Note that \( S_{i1}(\phi = 0) = S_{b0} \) (for \( j = i, e, b \)), at equilibrium, while \( S_{i1}(\phi = 0) = 0 \).

Eq.(19) has the form of a pseudo-energy-conservation equation, for a particle of unit mass, where the first term represents a kinetic energy term and \( S(\phi) \) is a pseudopotential energy function (assuming that the variable \( X \) plays the role of “time” and the potential \( \phi \) plays the role of a virtual “position coordinate”, in analogy). This formalism is reminiscent of the Sagdeev-type methodology \([49]\) for localized electrostatic excitations (collisionless shocks) in plasmas \([50]\); details can be found in related literature (see e.g. in Ref. \([50]\) for a thorough discussion), and are thus omitted here.

The analysis therefore consists in solving Eq.(19) (numerically) for the electrostatic potential \( \phi(X) \), and then calculating the remaining plasma variables (as functions of space), in the moving frame. Examples of the outcome of this procedure are presented in the parametric analysis that follows.

IV. EXISTENCE CONDITIONS FOR SOLITARY WAVES

It is anticipated, from previous applications of the above methodology in classical plasmas \([45, 50]\), that the soliton speed \( M \) must take values included in an interval \((M_1, M_2)\), for solutions to exist. The boundaries \((M_1, M_2)\) depend on the the particular aspects of the problem; here, the plasma configuration and the beam characteristics.

We will determine in the following the Mach number limitations and will then investigate the effect of the beam on the parameter regions where electrostatic waves may occur. Naturally, in every step in the analysis that follows, the (beam-free) limit \( \delta = 0 \) recovers the expressions and numerical values found in Ref. \([45]\) for electron-ion plasma.

The pseudopotential \( S \) must satisfy a number of conditions, in order for solutions to exist. First of all, one may easily check that \( S(\phi = 0) = \frac{dS(\phi)}{d\phi} \big|_{\phi=0} = 0 \), reflecting the physical fact that both the electric field and
the charge density are zero at equilibrium. Furthermore, the curve must have a maximum at the origin, implying $\frac{d^2S(\phi)}{d\phi^2}|_{\phi=0} < 0$, hence the origin is an unstable fixed point. Finally, we are interested in parameter values for which $S(\phi) < 0$ – as obvious from (19) – which is realised in the interval $0 < \phi < \phi_0$; here, $\phi_0$ say, denotes the first non-zero root of $S$, viz. $S(\phi_0) = 0$, which represents the maximum value of $\phi$ to be “visited” by the dynamics.

a. Minimum Mach number: the superacoustic condition. The curvature condition $\frac{d^2S(\phi)}{d\phi^2} \leq 0$ (see above) leads to the inequality:

$$\left(1 - \gamma_0 \delta\right) \frac{1}{M_t^2} - \frac{H_0}{1 - \mu_b H_0^2 M_t^2} + \frac{\delta}{\mu_b} \frac{1 - \alpha V_b \gamma_0^2 (M_1 - V_b)}{\gamma_0^2 (M_1 - V_b)^2} \leq 0 \quad (22)$$

The lower boundary for the Mach number, say $M_1$, is thus obtained by solving the equation $S^i(\phi = 0; M_1) = 0$ for $M_1$.

b. Maximum Mach number. A second physical requirement is associated with the reality of the state variables, i.e. the density variables $n_j$ and the fluid speed variables (for $j = e, i, b$). First of all, from the analytical expression for the ion fluid speed – see Eq. (A6) in the Appendix – we obtain an explicit requirement for $u_i$ to be real, in the form of the inequality:

$$\phi \leq \phi_{\text{max},i} = \frac{1}{\alpha} \left(1 - \sqrt{1 - \alpha M_t^2}\right) \quad (23)$$

In the non-relativistic limit $\alpha \ll 1$, this condition reduces to $\phi \leq \phi_{\text{max},i} = \frac{M_t^2}{2}$, which is the well known classical requirement [49].

Following a similar argument, from Eq. (A10) (in the Appendix) for the beam fluid speed, we find the following condition to be imposed, for reality:

$$\phi \leq \phi_{\text{max},b} = \frac{\mu_b}{\alpha} \left[\gamma_0 (1 - MV_b \alpha) - \sqrt{1 - M_t^2}\right] \quad (24)$$

In the nonrelativistic limit $\alpha \ll 1$, we obtain $\phi_{\text{max},b} = \frac{\mu_b}{\alpha} \left[\gamma_0 (1 - MV_b \alpha) - \sqrt{1 - M_t^2}\right]$, hence for $V_b = 0$, we recover $\phi_{\text{max},b} = \frac{M_t^2}{2}$, in agreement with the infinite compression limit in the classical case [49, 50]. We see that a maximum value must be imposed for the electrostatic potential $\phi$, viz. $\phi \leq \min\{\phi_{\text{max},i}, \phi_{\text{max},b}\} \equiv \phi_m$. In the above considerations, it is understood that $M < 1/\sqrt{\alpha} > 0$, a condition which indeed holds for all realistic parameter values to be adopted in the following.

In view of the above reality requirement(s), we shall impose the condition:

$$S(\phi_m) \geq 0 \quad (25)$$

where $\phi_m$ was defined above. The upper boundary $M_2$ is thus obtained by solving the equation $S(\phi = \phi_m; M_2) = 0$ (numerically) for $M_2$. 

FIG. 1: (Color online) The Mach number $M$ is depicted versus (a) the beam velocity $V_{b0}$ (for $\delta = 0.01$) and (b) beam density $\delta$ (taking $V_{b0} = 0.2$). We have considered different values of the (equilibrium) electron density $n_{0e}$ (as listed in the inset label) and $\mu_b = 1$ ($H^+$ beam).

In order to determine the soliton existence region, and to elucidate the role of the beam (characteristics), we have numerically solved the equations (22) and (25) for the limit values $M_1$ and $M_2$, respectively, assuming a positive hydrogen beam ($\mu_b = 1$), for various combinations of values for the beam speed ($V_{b0}$), the density ($\delta$) and the unperturbed electron density $n_{0e}$.

Fig. 1a shows the variation of $M_1$ with the ion beam velocity $V_{b0}$, for certain (fixed) values of $n_{0e}$, $\mu_b$ and $\delta$. We can see that $M_1$ increases with the beam velocity $V_{b0}$.

In an analogous manner, Fig. 1b shows that $M_1$ is an increasing function of the beam density $\delta$ (for given values of $n_{0e}$, $\mu_b$ and $V_{b0}$). In both cases, however, $M_1$ decreases.
FIG. 2: (Color online) The soliton existence region, i.e. the interval of the permitted Mach number $M$ values, is depicted with $n_{e0}$ in units of $10^{11}$ m$^{-1}$ (a) for different values of $V_{b0}$ with $\delta = 0.01$, (b) for different values of $V_{b0}$ with $\delta = 0.2$, (c) for different values of $\delta$ with $V_{b0} = 0.2$, and (d) for different values of $\delta$ with $V_{b0} = 0.5$.

upon increasing the density $n_{e0}$.

The permitted range of values for $M \in [M_1, M_2]$ was found numerically and is depicted in Fig. 2, against the electron density $n_{e0}$ (for given fixed values of $V_{b0}$, $\delta$, and $M$). Solutions occur between the lower and upper curves in this plot. We note that the upper curve decreases faster, for higher values of the electron density $n_{e0}$, until it crosses over. Solutions will not exist beyond this crossover point.

V. PARAMETRIC ANALYSIS

We have solved the equations (19) and (20) numerically for various values of the plasma configuration parameters ($n_{e0}$, $V_{b0}$, $\delta$, and $M$), keeping the value of $\mu_b$ fixed (to one). The results are shown in Figs. 3-8. We have studied the effect of the physical plasma parameters on the shape of the Sagdeev potential, the maximum amplitude of electrostatic potential $\phi_m$, the corresponding electric field $E$ and plasma state variables $n_e$, $u_e$, $n_i$, $u_i$, $n_b$ and $u_b$; these will be discussed in the following.

A. The effect of the equilibrium electron density

To study the effect of the asymptotic (equilibrium) electron density $n_{e0}$, we have plotted the pseudopotential $S(\phi)$, given by Eq. (20), for different values of $n_{e0}$ in Fig. 3. The corresponding electrostatic potential $\phi$ and the resulting ambipolar electric field $E$, in addition to the plasma state variables (namely, the electron density $n_e$, electron velocity $u_e$, ion density $n_i$, ion velocity $u_i$, ion beam density $n_b$ and ion beam velocity $u_b$) were found numerically, and are shown in Fig. 4. We see in Fig. 3 that the root of $S(\phi)$ increases monotonically with $n_{e0}$, suggesting stronger potential pulses at larger densities. Furthermore, the depth of the Sagdeev potential well increases with $n_{e0}$. We can see from Fig. 4a that the amplitude of the electrostatic potential (pulse) $\phi$ increases with $n_{e0}$, while the width decreases; the pulse therefore becomes narrower (steeper) for higher $n_{e0}$. An analogous variation of all other plasma state variables is visible in Figs. 4b-4h.

B. Beam velocity effect

We have plotted the Sagdeev pseudopotential $S(\phi)$ against $\phi$ in Fig. 5, for different values of the (equilibrium) beam fluid speed $V_{b0}$. Both the root of $S$ (i.e., the maximum value of the potential $\phi$ excitation) and the depth of the potential well are seen to decrease with larger $V_{b0}$. The corresponding plasma state variables were obtained numerically, and are shown in Fig. 6. We see that the amplitude (width) of all plasma variables increases (decreases) with larger beam velocity value.
FIG. 3: (Color online) The pseudopotential $S(\phi)$ is depicted in terms of the electrostatic potential $\phi$ for different values of the unperturbed electron density $n_{e0}$, in two cases: (a) $V_{b0} = 0$ and (b) $V_{b0} = 0.2$. We have assumed $\delta = 0.01$, $\mu_b = 1$, $M = 1.2$ everywhere.

C. The effect of the equilibrium beam density

Finally, we have varied the value of the ion beam density $\delta$ in order to study its effect on the shape of the Sagdeev potential in Fig. 7. Furthermore, its effect (for fixed speed $V_{b0}$) on the amplitude and the width of the associated electrostatic pulse and electric field is shown in Fig. 8. The conclusions to be drawn from this analysis are directly analogous to the ones deduced from varying the beam velocity in the previous paragraph, as qualitatively expected. Indeed, an increase in either the beam (fluid) speed or the beam density results in an increase in the beam (and, in fact, overall) current $J$, which therefore affects the propagation characteristics of electrostatic solitary waves. We have kept the value of the beam current very low, in our sets of numerical values considered, in respect of the electrostatic approximation (i.e., so as to justify having neglected dynamical magnetic field generation in our model).

VI. CONCLUSIONS

We have established a rigorous relativistic model for electrostatic excitations in ultradense plasma (assuming quantum degeneracy for the electrons), and we have used it as a basis to study the influence of a positive ion beam onto electrostatic solitary waves propagating in the plasma. Nonlinear analysis has revealed that positive potential $\phi$ (only) pulses may occur, in agreement with experiments on laser-plasma interactions [52, 53]. The existence domain (velocity, or Mach number interval) of solitary waves has been determined, and was shown to become slightly wider with an increase in beam density while, reversely, it “shrinks” dramatically with an increase in beam velocity (for fixed density). Finally, we have studied the effect of intrinsic plasma parameters on the structural properties (shape) of solitary waves.

Our nonlinear analysis has focused on large electrostatic excitations, and thus imposed no restriction on their amplitude, which was left arbitrary throughout the study. An independent, linear analysis would have led to small-amplitude harmonic solutions, i.e. Fourier modes (electrostatic waves), along the lines proposed e.g. in Ref. [46] (in the absence of a beam). We point out that the latter study led to a dispersion relation which was characterized by two distinct dispersion branches (for the real frequency $\omega$ as a function of the wavenumber $k$), namely an acoustic one and a(n) (Langmuir-like) electron-plasma branch. In the presence of an ion beam, however, the dispersion relation becomes a sixth-order polynomial, whose analysis reveals the existence of a third (beam-driven) mode [54]. In addition to this qualitative change, due to the beam, an imaginary part $\gamma$ arises in the (now complex) frequency, say $\omega = \omega_r + i\gamma$, in a small window of values of the wavenumber $k$, hence a linear instability develops [54]. Admittedly, both the beam-ion component number density and velocity were assumed to be small, in respect of the electrostatic approximation (i.e. in order for the total current to be negligible, hence magnetic field generation to be suppressed), hence the growth rate of this linear instability should be thought of as small, for practical situations. However, a stronger beam should lead to a growing mode which might be dominant and eventually destabilize the electrostatic wave. From a purely energetic viewpoint, this would represent a loss term, which should eventually destabilize not only linear waves, but also localized lumps of energy (solitary waves) occurring in the system.

Apart from the aforementioned (linear) beam instability, one might expect solitary wave propagation to be affected by nonlinear beam-plasma or kinetic instabilities, such as Buneman type instabilities [55, 56] or even Landau damping [57, 58], a kinetic effect expectedly overlooked in the fluid picture adopted herein.

Our results are expected to be important in dense plasmas arising from solid target irradiation by ultrahigh-intensity laser beams and also in extreme astrophysical environments, where high-density plasma models are rela-
The solution $X$ satisfies the boundary condition $\lim_{X \to \pm \infty} \phi = 0$. By integrating the equation of motion (19) for the ions, we obtain

$$\phi = M \gamma_u u_i - \frac{\gamma_v}{\alpha} + \frac{1}{\alpha},$$  \hspace{1cm} (A4)$$

i.e.

$$[M^2 + \alpha \left( \frac{1}{\alpha} - \phi \right)^2] u_i^2 - \frac{2M}{\alpha} u_i \phi = \frac{2M}{\alpha} [1 - \left( \frac{1}{\alpha} - \phi \right)^2] = 0.$$  \hspace{1cm} (A5)

The solution for the ion fluid speed reads:

$$u_i = \frac{M}{\sqrt{\frac{M^2}{\alpha^2} - \frac{2M}{\alpha} \phi - \frac{1}{\alpha} (1 - \frac{1}{\alpha} - \phi)^2}},$$  \hspace{1cm} (A6)$$

where we chose to proceed with the solution satisfying the boundary condition $\lim_{X \to \pm \infty} u_i = 0$. A thorough analysis of the quantity under the square root reveals that reality of the ion fluid speed (A6) imposes

$$\phi \leq \frac{1}{\alpha} \left( 1 - \sqrt{1 - \alpha M^2} \right).$$  \hspace{1cm} (A7)$$

In an analogous manner, upon integrating the equation of motion (19) for the beam (fluid), we obtain:

$$\frac{1}{\mu_b} \phi = M (\gamma_b u_b - \gamma_b V_0) \frac{\gamma_b}{\alpha} + \frac{\gamma_b}{\alpha},$$  \hspace{1cm} (A8)$$

or, rearranging,

$$u_b = \frac{M}{\sqrt{\frac{M^2}{\alpha^2} \left( \gamma_b (MV_0 - \frac{1}{\alpha}) + \frac{1}{\mu_b} \phi \right)^2}} - \left( \gamma_b (MV_0 - \frac{1}{\alpha}) + \frac{1}{\mu_b} \phi \right)^2 \right),$$  \hspace{1cm} (A10)$$

satisfies the boundary condition $\lim_{X \to \pm \infty} \phi = 0$ and

$$\lim_{X \to \pm \infty} u_b = V_0.$$
to be a real quantity, the condition

$$\phi \leq \frac{\mu_0}{\alpha}\left[n_0(1 - MV_0\alpha) - \sqrt{1 - M^2}\right]$$  \hspace{1cm} (A11)

must hold.

Combining Eqs. (A1) and (A6), we obtain the ion fluid density $n_i(\phi)$ and speed $u_i(\phi)$ in terms of the potential $\phi$ (for a given value of $M$). The beam-ion fluid properties are obtained in an analogous manner from (A3) and (A10).

Integrating the equation of motion of the electrons (19), we obtain:

$$\frac{\mu_e}{\alpha} \phi = \left[\gamma_e \sqrt{1 + \frac{\alpha}{\mu_e} n_e^2(1 - \alpha M u_e) - H_0}\right]$$  \hspace{1cm} (A12)

Finally, in order to obtain the electron fluid speed in terms of $\phi$, we may substitute Eq. (A14) into Eq. (A2).

Combining the above relations for the density variables into Poisson’s equation (19), we find, for the electrostatic potential $\phi$, a differential equation in the form:

$$\frac{d^2 \phi}{dX^2} = f(\phi),$$  \hspace{1cm} (A15)

where the function $f$ in the RHS is given by:

$$f(\phi) = -\frac{\alpha M^2}{1 - \alpha M^2} \sqrt{\alpha M^2 + \frac{\mu_e}{\alpha} \left[\sqrt{1 - (\xi_0^2 + H_0)^2 - \alpha M^2 (1 - \xi_0^2)}\right]^2 - \frac{4\xi_0^2 (1 - \alpha M^2) \alpha M^2}{2\xi_0^4 (1 - \alpha M^2)}} - \frac{(1 - \gamma_{\text{ion}}) M}{M - \frac{\mu_e}{\alpha} \left[\frac{M^2 + \alpha (\frac{1}{\mu_e} - \phi)^2}{\sqrt{\alpha M^2 + \frac{\mu_e}{\alpha} (\frac{1}{\mu_e} - \phi)^2}}\right] - \delta \frac{M}{M - \frac{\mu_e}{\alpha} \left[\frac{M^2 + \alpha (\gamma_{\text{ion}}(MV_{\text{ion}} - \frac{1}{\mu_e} + \frac{1}{\mu_e} \phi))}{\sqrt{\alpha M^2 + \frac{\mu_e}{\alpha} (\gamma_{\text{ion}}(MV_{\text{ion}} - \frac{1}{\mu_e} + \frac{1}{\mu_e} \phi))^2}}\right]^2}}$$  \hspace{1cm} (A16)

Multiplying by the derivative $d\phi/dX$ and integrating, we obtain precisely Eq. (19):

$$\frac{1}{2} \left(\frac{d\phi}{dX}\right)^2 + S(\phi) = 0.$$
