Biodegradable hydrogels composed of oxime crosslinked poly(ethylene glycol), hyaluronic acid and collagen: a tunable platform for soft tissue engineering

In situ crosslinking hydrogels are attractive for application as injectable hydrogel-based tissue scaffolds that adapt to fill patient-specific cavities. Oxime click chemistry was used to crosslink hydrogels that were biodegradable, soft, and supportive of cell adhesion. Linear poly(ethylene glycol)s (PEGs, Mn 2 or 4 kDa) terminated at both ends with aminooxy moieties and hyaluronic acid (HA, Mn 2 MDa) derivatives displaying aldehydes were non-toxic towards primary Schwann cells. The PEG and HA derivatives form oxime crosslinked hydrogels with mechanical and swelling properties that were tunable based on the composition of the hydrogels to values analogous to soft tissues such as those found in the central or peripheral nervous system. Gels incorporating collagen-1 supported the adhesion of human mesenchymal stem cells (HMSCs). Such chemistry has the potential to generate clinically relevant injectable hydrogels for minimally invasive personalized medical procedures in the central or peripheral nervous systems.

Keywords: Biodegradable; biomaterials; biomimetic mechanical properties; central nervous system; peripheral nervous system; in vitro cell culture; injectable hydrogels; tissue engineering

1. Introduction

Hydrogels are an important class of biomaterials that can be used for a variety of biomedical applications such as tissue engineering or drug delivery [1]. In situ crosslinking hydrogels have attracted significant attention for their potential use as injectable tissue scaffolds that adopt the shape of the cavity in which they are injected [2]. Additionally, injectable hydrogels represent useful platforms for the development of patient-specific tissue scaffolds for personalized medicine [3, 4].

A variety of chemistries have been investigated for the preparation of in situ gelling hydrogels, including chemical-, enzymatic-, photo-, physical- and
Each crosslinking methodology has associated advantages and disadvantages (e.g., kinetics and cytotoxicity, respectively). The “click” chemistry philosophy has revolutionized the preparation of polymer-based biomaterials. Click chemistry has been applied to polymers of natural or synthetic origins with many different architectures including linear (e.g., PEG, polysaccharides, proteins), branched (e.g., dendrimers, graft polymers) and macrocyclic polymers. Hawker and co-workers reported seminal early work describing the use of copper-catalyzed click reactions to generate hydrogels with biomedically relevant mechanical properties. The maximum true stress and extension to break were tuned simply and rationally by the molecular weight of the PEG; indeed, variation of the molecular weight of the PEG between 3.4 and 10 kDa allowed the maximum true stress to be tuned between ca. 700 to ca. 2400 kPa, and extension to break to be tuned between 400 % and ca. 1500 kPa. A drawback of this methodology is the toxicity of the copper, however this can be removed simply via exhaustive washing with copper chelating agents such as ethylenediaminetetraacetic acid (EDTA) after the gel is formed. A variety of copper-free click reactions were subsequently developed (including strain-promoted azide-alkyne cycloadditions, thiol-ene chemistry, thiol-yne chemistry, Diels-Alder reactions, tetrazole-alkene photo-click reactions, tetrazine-nobornene reactions, thiol Michael addition) that circumvent the toxicity of the copper, and these chemistries have been applied to the formation of bulk hydrogels or hydrogel-based beads/particulates which have potential application in either drug delivery or tissue engineering, and are discussed in depth in a number of papers and reviews.

The various click chemistries have been applied to prepare HA-based hydrogels. Indeed, copper-catalyzed click reactions produced HA hydrogels with elastic moduli in the range of 0.5-4 kPa, or HA/gelatin/chondroitin sulphate gels with elastic moduli.
of ca. 7 kPa [21]. Copper-free click reactions have also been used, and thiol-ene chemistry used to produce HA-based micro/nanospheres [22], thiol-yne chemistry between HA and poly(vinylalcohol) to produce hydrogels with storage and loss moduli of ca. 0.6 kPa and 0.1 kPa respectively [23], thiol-nobornene chemistry has been used to generate HA-based hydrogels with elastic moduli in the range of 1-70 kPa [24], and Diels-Alder reactions have been used to generate hydrogels composed of HA and PEG with elastic moduli in the range of 2-110 kPa [25, 26], and thiol Michael addition chemistry has been used to prepare hydrogels composed of HA and PEG with storage and loss moduli of ca. 1 kPa and 10 Pa respectively [27].

The hydrazone [28] and oxime [29-31] bond formation click reactions (between aldehydes or ketones and acylhydrazine or aminooxy derivatives, respectively) are also popular for the preparation of hydrogels. Although this class of “click” reactions are clearly not bioorthogonal (e.g., paraformaldehyde is used to fix cells for histology [32], ketones can react with the ε-amino group of lysine [33], and aminooxy-functionalized tags are used to identify post-translationally-carbonylated proteins in proteomic studies) [34], hydrogels prepared using aldehyde-aminooxy oxime “click” reactions are interesting because the product of the reaction (an oxime) is more stable than Schiff bases formed between either aldehydes or ketones and amines displayed on peptides or proteins in the biological milieu (that yield constitutionally dynamic mixtures of products) [35, 36]. Such inherently adaptable chemistry can generate in situ crosslinking hydrogels that are clinically relevant soft biomaterials for personalized medicine, and are of interest for application within the nervous system [37-40].

Injectable hydrogels based on polysaccharides and/or PEG derivatives displaying aldehydes and hydrazides reported by the groups of Kohane, Langer, Lowman, Prestwich and Anseth [41-45]. Particularly pertinent examples include those
from Jia and coworkers who used PEGs terminated with aldehydes and hydrazine functionalized HA to prepare gels with elastic moduli between 100 and 2000 Pa depending upon the composition of the gels [46, 47]. We point the interested reader towards excellent reviews on HA-based hydrogels [48-50].

Grover and Maynard reported the concomitant application of aldehyde-aminooxy oxime “click” reactions and ketone-aminooxy oxime “click” reactions to prepare injectable soft cell-adhesive PEG-based hydrogels. Aminooxy-terminated PEGs were crosslinked with cytotoxic glutaraldehyde, and rendered cell adhesive via reaction of some of the aminooxy termini with ketone-functionalized peptide derivatives containing the integrin ligand arginine-glycine-aspartic acid (RGD). Interestingly, the cytotoxicity of glutaraldehyde was minimized due to the high reactivity of the aminooxy functional groups towards the aldehydes, and cells were shown to adhere and proliferate on the surface of the gels [29]. Thereafter, Grover and Christman reported the use of analogous chemistry to prepare injectable PEG-, alginate- and HA-based hydrogels for catheter-assisted delivery to the hearts of rats [51]. Becker and co-workers reported the application of ketone-aminooxy oxime “click” reactions to prepare injectable soft PEG-based hydrogels, and subsequently used Huisgen 1,3-cycloaddition and thiol-ene chemistry to pattern them with peptides containing RGD motifs [52], and such substrates have enormous potential for in vitro studies such as high throughput drug screening.

While RGD is commonly used to render non-adhesive materials cell adhesive, there are reports of unintentional side effects of RGD modification (e.g., modifying cell adhesion, spreading, or migration because the RGD motifs are not displayed with biomimetic distributions [53-57]) that may diminish their prospects for clinical translation. We believe that incorporation of cell adhesive proteins such as alpha-1 type
collagen (COL-1) will circumvent these problems, because the sequence and spacing of cell adhesive peptide motifs in such proteins are conserved over a variety of species, thereby facilitating normal cell behaviour.

Herein we report the results of our investigations of biodegradable in situ crosslinking hydrogels based on the oxime “click” reaction between linear PEGs terminated at both ends with aminooxy moieties with HA derivatives displaying aldehydes, and optionally, COL-1. With a view to the implantation of the hydrogels via minimally invasive techniques in soft tissues such as those comprising the central and peripheral nervous systems, we assess the toxicity of the PEG and HA derivatives to primary neuroglia (supporting cells of the nervous system), and the mechanical properties of the hydrogels to assure that they are mimetic of human nervous tissues. In-situ crosslinking hydrogels capable of supporting the adhesion of stem cells are being investigated for both drug delivery and tissue engineering [58]. It is conceptually possible to aid neural tissue regeneration and repair via stem cell therapies, which may be able to treat Huntington’s disease, Parkinson’s disease and other neurological disorders [59-65]. Multipotent HMSCs are a potentially clinically-relevant autologous source of stem cells currently under investigation for a variety of personalized medical devices [66-70], consequently we assessed their adhesion on the hydrogels.

2. Materials and Methods

2.1. Materials

Unless otherwise stated, all chemicals for chemical synthesis were of ACS grade, purchased from Sigma-Aldrich and used as received without further purification. For cell culture, all reagents were purchased from Invitrogen (Carlsbad, CA) unless
otherwise noted. Human Mesenchymal Stem Cells (HMSCs) were purchased from Lonza (Gaithersburg, MD).

2.2. Synthetic and Analytical Methods

$^1$H and $^13$C NMR spectra were recorded on a Varian Mercury 400 MHz NMR spectrometer, using residual solvent $^1$H peaks as internal references for the $^1$H NMR spectra and the solvent $^{13}$C peaks as references for the $^{13}$C NMR spectra. The following notation is used for the $^1$H NMR spectral splitting patterns: singlet (s), doublet (d), multiplet (m), broad (br).

2.3. Synthesis

2.3.1. Synthesis of Phthalimide-Terminated PEGs

Phthalimide-terminated PEGs were synthesized by adaptation of the literature [71]. To solutions of PEG diols (2 mmol, with average molecular weights of either 2 or 4 kDa) in CH$_2$Cl$_2$ was added diisopropylazodicarboxylate (DIAD, 9.6 mmol), N-hydroxyphthalimide (11.2 mmol), and triphenylphosphine (PPh$_3$, 11.2 mmol). The resulting mixture was stirred for 24 h at room temperature under an atmosphere of argon. Then the reaction mixture was added dropwise to cold diethylether (Et$_2$O, 4 ºC) that was rapidly stirred, inducing precipitation of the polymers and facilitating their isolation by vacuum filtration. The powders were washed with cold Et$_2$O and dried under high vacuum for 48 hours. This process was repeated until $^1$H NMR in d$_6$-DMSO indicated that the reaction was complete. Phthalimide-terminated PEG-2k was isolated in a yield of 23.5%, whereas the phthalimide-terminated PEG-4k was isolated in a yield of 82%. $^1$H NMR (400 MHz, d$_6$-DMSO): δ 3.4-3.55 (br m, C$_2$H$_2$O, PEG), 3.7-3.75 (br m, 4H, C$_2$H$_2$O, PEG), 4.25-4.3 (br m, 4H, C$_2$H$_2$O, PEG), 7.86 (br s, 8H, Ar-H, phthalimide).
2.3.2. Synthesis of Aminooxy-Terminated PEGs

Aminooxy-terminated PEGs were synthesized by adaptation of the literature [71]. The phthalimide moieties at the PEG termini were cleaved by the addition of hydrazine hydrate (10 moles of hydrazine hydrate per mole of PEG chains) to solutions of phthalimide-terminated PEGs in dichloromethane. The reaction mixtures were stirred under argon at room temperature for 24 hours, followed by filtration to remove the phthalhydrazide byproduct, followed by evaporation of the volatiles in vacuo. This process was repeated for another 72 hours after which $^1$H NMR in $d_6$-DMSO indicated that the reaction was complete. Aminooxy-terminated PEG-2k was isolated in a yield of 25%, whereas the aminooxy-terminated PEG-4k was isolated in a yield of 52%. $^1$H NMR (400 MHz, $d_6$-DMSO): $\delta$ 3.45-3.7 (br m, CH$_2$O, PEG), 5.97 (br s, 4H, ONH$_2$).

2.3.3. Synthesis of Hyaluronic Acids Displaying Aldehydes

HA-ALDs were synthesized by adaptation of the literature [44]. 1.0 g HA (MW ca. 2 MDa) was dissolved in ultrapure (Millipore) water (100 mL) at a concentration of 10 mg mL$^{-1}$. Sodium periodate (0.535 g, 2.5 mM) was added and the reaction was stirred for 1, 2 or 24 hours at room temperature in the dark (to prepare HA-ALD-1, HA-ALD-2 and HA-ALD-24 respectively). Unreacted periodate was quenched by the addition of ethylene glycol (140 $\mu$L, 2.5 mM) and the reaction was stirred for 1 hour at room temperature in the dark. Low molecular weight contaminants were removed via exhaustive dialysis against ultrapure water in ready-to-use dialysis sacks (MWCO 3.5 kDa, Spectra/Por®, Spectrum Labs, USA), for 4 days with water exchange at least 3 times daily. HA-ALD-1, HA-ALD-2 and HA-ALD-24 were isolated by lyophilization in yields of ca. 50, 40 and 30 % by mass respectively.
2.4. Cytotoxicity of PEG and HA Derivatives

The cytotoxicity of the PEG and HA derivatives towards neonatal rat Schwann cells isolated from sciatic nerves (purchased from ScienCell, Carlsbad, CA) was determined using a Cell Titer-Glo® Luminescent Cell Viability Assay (Promega, USA). Full details are found in Appendix 1.

2.5. Hydrogel Preparation

Stock solutions of HA-ALDs (1 wt % in PBS) and aminooxy-terminated PEGs (0.117 M in PBS) were prepared. Gels were prepared by mixing the various HA-ALDs and aminooxy-terminated PEGs in three different volume ratios (HA-ALDs:aminooxy-terminated PEGs): 10:1, 15:1 or 20:1 respectively. Typically, a volume of ca. 150 µL of pre-gel solutions was injected into cylindrical molds (with diameters of 9 mm and heights of 1.7 mm) formed by attaching silicone isolators with adhesive on one side (supplied by Grace Bio-Labs, Bend, OR) to glass slides. Optionally, rat tail COL-1 (BD Biosciences) was added at a final concentration of 50, 100 or 200 µg mL⁻¹ of gel.

2.6. Fourier Transform Infrared Spectroscopy (FTIR)

Infrared spectroscopy was carried out on a Thermo Scientific Nicolet 380 FTIR Spectrometer (Thermo Fisher Scientific Inc., USA). Spectra were recorded for 16 scans in ATR mode at 21 °C, with a 1 cm⁻¹ resolution. Spectra were corrected for background and atmosphere using OMNIC software provided with the spectrometer.

2.7. Hydrogel Swelling and Flory-Rehner Calculations

The swelling properties of cylindrical gels prepared as described in section 2.5. (i.e., with diameters 9 mm and heights of 1.7 mm) were determined and Flory-Rehner calculations based on these data were carried out in accordance with the literature [72-80]. Full details are found in Appendix 1.
2.8. Mechanical Testing
Compressive tests on cylindrical gels prepared as described in section 2.5. (i.e., with diameters 9 mm and heights of 1.7 mm) were performed using an Instron Materials Testing Machine 5543 Series Single Column System (Instron, Norwood, MA) with Bluehill 2 software. Full details are found in Appendix 1.

2.9. In Vitro Degradation Studies
Degradation of cylindrical gels prepared as described in section 2.5. (i.e., with diameters 9 mm and heights of 1.7 mm) upon exposure to hyaluronidase (10 U mL⁻¹ in PBS) was studied over 25 days. Full details are found in Appendix 1.

2.10. Uronic Acid Quantification Assay
The quantity of uronic acid released upon degradation of the gels in vitro was assayed using a methodology adapted from the uronic acid carbazole reaction reported by Cesaretti and co-workers [81]. Full details are found in Appendix 1.

2.11. Cell Culture
HMSCs were cultured on the hydrogels in under 3 mm of DMEM supplemented with 10 % fetal bovine serum, 100 U ml⁻¹ penicillin, 100 µg ml⁻¹ streptomycin, 0.25 µg ml⁻¹ amphotericin, 0.1 mM non-essential amino acids, and 1 ng ml⁻¹ basic fibroblast growth factor. Full details are found in Appendix 1.

3. Results and Discussion

3.1. Polymer Synthesis, Characterization and Cytotoxicity
Linear aminooxy-terminated PEGs were prepared via adaptation of the methodology described by the Francis group (Scheme 1) [71]. Phthalimide-terminated PEGs (with Mn of ca. 2 or 4 kDa) were prepared via the reaction of hydroxyl-terminated PEGs with
N-hydroxyphthalimide, triphenylphosphine (Ph₃P) and diisopropyl azodicarboxylate (DIAD), and purified by precipitation. Phthalimide-terminated PEG-2k was isolated in a yield of 23.5%, whereas the phthalimide-terminated PEG-4k was isolated in a yield of 82%. ¹H NMR recorded in d₆-DMSO was used to confirm the quantitative conversion of the hydroxyl-terminated PEG starting materials to the phthalimide-terminated PEGs; with peaks at δ 3.45-3.7 ppm corresponding to protons on the backbone of the PEG chains and the peak at δ 7.86 ppm corresponding to the protons on the aromatic phthalimide group at the termini of the PEG chains.

Exposure of the phthalimide-terminated PEGs to hydrazine cleaved the phthalimide groups and facilitated purification of the aminooxy-terminated PEGs via filtration to remove the phthalhydrazide byproduct, followed by evaporation of the volatiles under vacuum. Aminooxy-terminated PEG-2k was isolated in a yield of 25%, whereas the aminooxy-terminated PEG-4k was isolated in a yield of 52%. ¹H NMR recorded in d₆-DMSO was used to confirm the quantitative conversion of the phthalimide-terminated PEGs to the aminooxy-terminated derivatives; with peaks at δ 3.45-3.7 ppm corresponding to protons on the backbone of the PEG chains and the peak at δ 5.97 ppm corresponding to the protons on the aminooxy group at the termini of the PEG chains.

HA derivatives displaying aldehydes were prepared by adaptation of the methodology reported by the Langer group [44]. HA (Mn of ca. 2 MDa) was exposed to sodium periodate for 1, 2 or 24 hours, after which the reaction was quenched with ethylene glycol. The product was purified by dialysis against water and lyophilized. The resulting aldehyde-displaying HA derivatives are hereafter referred to as HA-ALD-1, HA-ALD-2 and HA-ALD-24 depending upon the number of hours to which they were
exposed to sodium periodate, and were isolated in yields of ca. 50, 40 and 30 % by mass respectively.

In-situ crosslinking hydrogels have potential application in a variety of biomedical technologies, including drug delivery and tissue engineering [1-4]. With a view to the implantation of the in-situ crosslinking hydrogels described herein in neural tissues, we assessed the cytotoxicity of the PEG and HA derivatives towards glial cells from the peripheral nervous system, specifically, primary Schwann cells isolated from neonatal rats in preference to immortalized cell lines. Schwann cells were incubated with various concentrations of PEG and HA derivatives for 24 hours, after which cell viability was assessed using a Cell Titer-Glo® Luminescent Cell Viability Assay, and viability is reported relative to cell adhesive plasma-treated tissue culture plastic (arbitrarily assigned to be 100 %). Cell viability was high in all cases, but observed to decrease moderately (to ca. 90 %) at higher concentrations (6 mg mL⁻¹) of the PEG and HA derivatives (Figure 1). The high viabilities of the primary neuroglia suggest that the PEG and HA derivatives described herein are promising building blocks for in-situ crosslinking hydrogels for application as drug delivery devices or tissue scaffolds for the nervous system.

3.2. Hydrogel Preparation and Physicochemical Characterization

Hydrogels were formed by mixing stock solutions of the various components in phosphate buffered saline (PBS, pH 7.4) prior to injection into flexible PDMS molds. The gel compositions studied here are presented in Table 1. Crosslinking was observed to occur within seconds of mixing the PEGs and HA-ALD-24, with crosslinking being complete within seconds for the gels incorporating aminooxy-terminated PEG-4k and minutes for the gels incorporating aminooxy-terminated PEG-2k. Such swift crosslinking is ideal for application as either drug delivery devices or tissue scaffolds.
for the nervous system. For consistency, characterization of the gels via various techniques was carried out 24 hours after their formation.

Successful crosslinking of the various aminooxy-terminated PEGs with the aldehyde-functionalized HA derivatives was confirmed by the appearance of a peak at 1672 cm\(^{-1}\) in the infrared absorption spectrum of lyophilized hydrogels, which corresponds to the aliphatic oxime bonds that crosslink the hydrogels [51] (Figure 2).

The combination of various ratios of the PEG and HA derivatives facilitated the development of oxime crosslinked hydrogels with tunable mechanical and swelling properties. The mechanical properties of the resulting hydrogels and the results of the Flory-Rehner calculations based on swelling experiments are presented in Table 1. The mechanical properties of biomaterials are known to play an important role in the way in which cells interact with them both in vitro and in vivo [82-85], therefore the mechanical properties of the hydrogels upon exposure to compressive or shear stress were examined. The compressive moduli, \(E\), of the hydrogels were between 2 to 12 kPa, analogous to soft tissues of the nervous system (e.g., brain has a compressive modulus of ca. 0.5 to 10 kPa) [86-91]. There was no clear trend in the compressive moduli for the gels incorporating low molecular weight (2 kDa) aminooxy-terminated PEG. However, gels incorporating the higher molecular weight (4 kDa) PEG analogue displayed compressive moduli that increased with increasing amounts of PEG, suggesting more efficient crosslinking of the hydrogels. Similar trends were observed for the storage and loss moduli of the hydrogels as assessed via rheology, with gels incorporating the low molecular weight PEG displaying storage moduli of ca. 400 to 600 Pa, and loss moduli of ca. 6 to 24 Pa (akin to those reported by Grover and Christman [51]), and a selection of other HA-based hydrogels [20-27, 46, 47]; whereas gels incorporating the higher molecular weight PEG displaying storage moduli of ca.
140 to 2870 Pa (akin to those reported by Collins and Birkinshaw [92] and others [20-27, 46, 47]), and loss moduli of ca. 6 to 57 Pa, both of which increased with increasing amounts of PEG (Table 1 and Appendix 1 Figure A1). Importantly, these properties mimic the human nervous system (e.g., human brain has a storage modulus of ca. 1000 to 3100 Pa, and a loss modulus of ca. 400 to 2500 Pa) [86-91], and are in the range of other HA-based hydrogels [20-27, 46, 47, 92]. These observations were supported by results from swelling experiments and Flory-Rehner calculations (Table 1). The effective crosslink density, $v_e$, calculated for the hydrogels were ca. $5 \times 10^{-6}$ mol cm$^{-3}$, and found to increase with increasing amounts of PEG, and, concomitantly, the swollen hydrogel mesh sizes in PBS, $\xi$, calculated for the hydrogels were ca. 2 nm and found to decrease with increasing amounts of PEG and therefore crosslinking density. These values are consistent with the literature for analogous HA-based hydrogels [76].

Gels formed using HA-ALD-1 or HA-ALD-2 (gels 7-12, Appendix 1, Table A1) gelated more slowly (over the duration of minutes to hours), and tended to have compressive moduli that were lower than those formed using HA-ALD-24, which indicates that the duration of exposure of the HA to the oxidizing reagent (sodium periodate) determines the number of aldehydes generated on the backbone of the HA and thereby the crosslinking density within the gel. It may therefore be possible to tune the mechanical properties of the gels by varying the duration of exposure of the HA to sodium periodate, potentially facilitating the preparation of hydrogels with mechanical properties matching specific soft tissues. For example, this could simply be achieved by quenching the periodate oxidation reaction with ethylene glycol at specific time points (e.g., 1, 3, 12, 24, 48, 72, 96 hours). It would be expected that shorter oxidation times would yield hyaluronic acids displaying fewer aldehyde moieties and generate softer gels, whereas those oxidized for longer periods would yield hyaluronic acids displaying
more aldehyde moieties (i.e. more sites for crosslinking with aminooxy-terminated
PEGs) and generate less flexible gels; further, after very long periods of oxidation the
molecular weight of the hyaluronic acid may decrease to the point at which the gels
would be weaker (however, this is outside the scope of the present study).

3.3. In Vitro Degradation and Cell Culture

It is impossible to accurately reproduce the conditions that materials encounter
when implanted in vivo in the laboratory, but in vitro degradation studies are useful to
confirm the potential for the gels to degrade upon exposure to enzymes found in vivo.
Consequently, gel degradation upon exposure to a high concentration of hyaluronidase
(10 U mL\(^{-1}\) in PBS) was studied over a time period of twenty five days by both mass
loss and an assay that quantified the amount of uronic acid released [81]. Mass loss for
gels composed of HA-ALD-24 and aminooxy-terminated PEG-2k or PEG-4k
derivatives (Figure 3) was observed during the first week and continued over the entire
duration of the assay, reaching approximately 40% loss after 25 days for all of the gel
compositions, albeit with no clear trend based upon the crosslinking density. The by-
product of the enzymatic degradation of HA is uronic acid, and the amount released
increased as the gels masses were concomitantly found to decrease (Figure 4), and was
typically on the µg regime (up to ca. 10% of the HA content of each gel over the period
of the 25 day assay), thereby confirming that enzymatic degradation of the HA in the
gel is possible. Furthermore, gels formed using HA-ALD-1 or HA-ALD-2 with the
aminooxy-terminated PEG-4k derivative, were observed to degrade more quickly under
the same experimental conditions (Appendix 1, Figure A2 and A3); logically, the
degradation of these mechanically weaker gels (Appendix 1, Table A1) is related to
their lower level of crosslinking, further supporting our suggestion that it may be
possible to tailor the properties of the gels to match specific tissues.
As noted above, researchers are currently investigating the feasibility of stem cell therapies (including multipotent HMSCs as a clinically-relevant autologous source of stem cells) to aid neural tissue regeneration and repair, targeting Huntington’s disease, Parkinson’s disease and other neurological disorders [66-70]. Consequently, we prepared hydrogels based on gels 1-6 incorporating various amounts of COL-1 (for precise compositions see Appendix 1, Table A2, gels 13-30) and confirmed the viability of HMSCs adhered on the surface of the after 48 hours of culture. Cells were seeded on gels composed of various ratios of aminooxy-terminated PEGs, HA-ALD-24, and COL1 (Figure 5) exhibited spread morphologies and the cell viability was greater than 88 % for all of the formulations tested (gel-specific values are shown in Figure 6). The high viabilities of the primary HMSCs on the in-situ crosslinking hydrogels described herein suggests that they are promising for application as personalized medical devices within the nervous system.

4. Conclusion

In conclusion, we report biodegradable in situ crosslinking hydrogels with biomimetic mechanical properties that are well-suited for application in neural tissues [93-95]. Oxime click chemistry was used to crosslink linear PEGs terminated at both ends with aminooxy moieties and HA derivatives displaying aldehydes. The PEG and HA derivatives were shown to have low cytotoxicities towards primary neuroglia (supporting cells in the peripheral nervous system, namely, Schwann cells). The mechanical and swelling properties were found to be tunable based upon hydrogel composition and mimetic of human nervous tissues. Gels incorporating COL1 supported the adhesion of HMSCs. Such hydrogels have the potential for application as personalized medical devices in the human nervous system, and we foresee their
application as injectable matrices for peripheral nerve tissue engineering, or indeed as a biodegradable reservoir for a therapeutic (e.g. an anti-inflammatory drug).

Appendix 1

Materials and Methods

Materials

Unless otherwise stated, all chemicals for chemical synthesis were of ACS grade, purchased from Sigma-Aldrich and used as received without further purification. For cell culture, all reagents were purchased from Invitrogen (Carlsbad, CA) unless otherwise noted. Human Mesenchymal Stem Cells (HMSCs) were purchased from Lonza (Gaithersburg, MD).

Cytotoxicity of PEG and HA Derivatives

Neonatal rat Schwann cells isolated from sciatic nerves were purchased from ScienCell (Carlsbad, CA). Cells were grown on tissue culture plastic and maintained in high glucose DMEM medium supplemented with 10% fetal bovine serum, 10 μg ml\textsuperscript{-1} bovine pituitary extract (Invitrogen, Carlsbad, CA), and 2 μM forskolin (Sigma-Aldrich, St. Louis, MO). To maintain consistent phenotype and cell purity, only cultures between passages 4–8 were used for experiments and purification was confirmed at >90% with S100 staining. Cultures reaching 80% confluency were detached with 0.25% Trypsin-EDTA for 2 min, centrifuged at 800 rpm for 4 min, resuspended in fresh medium, and seeded onto new tissue culture plastic. Medium was changed every third day and kept at
37 °C with 5% CO₂ in a humid incubator. The Cell Titer-Glo® Luminescent Cell Viability Assay (Promega, USA) was used to determine the cytotoxicity of the hydrogel components. A standard calibration curve for the number of viable Schwann cells was plotted to define the quantitative relationship between the observed luminescence and the number of viable cells. Cells were seeded in 48 well plates with 100 µL of media and 100 µL of Cell Titer-Glo® reagent. After incubation for 30 minutes, 100 µL of supernatant was transferred to a 96 well plate and a Synergy HT Multi-Mode Microplate Reader (Biotek, USA) was used to analyze the luminescence of the samples.

To assay the effect of the HA-based and PEG-based constituents of the hydrogels, Schwann cells were seeded in 48 well plates at 2000 cells per well with 200 µL of media. An additional 200 µL of a solution of an appropriate quantity of HA derivatives or PEG derivatives in media was added and the cells incubated for 24 hours at 37 °C, 95% humidity, and a CO₂ content of 5%. Thereafter, the supernatant was removed and 100 µL of fresh media and 100 µL of Cell Titer-Glo® reagent was added to each well. After incubation for 30 minutes, samples were taken for measurement. A standard calibration curve for the number of viable cells was plotted to define the quantitative relationship between the observed luminescence and the number of viable cells; n = 3.

**Hydrogel Swelling and Flory-Rehner Calculations**

Cylindrical gels prepared as described in section 2.5. (i.e., with diameters 9 mm and heights of 1.7 mm) were allowed to crosslink in the hydrated state for 24 hours, and then dried until a constant dry mass \( M_{dry} \) was reached (ca. 48 hours). The gels were swelled with PBS (1 mL) in pre-weighed tubes for 24 hours. Excess PBS was removed and the swollen mass in PBS \( M_s \) recorded. The swelling ratio based on mass \( Q_M \) was then determined by dividing the swollen mass in PBS by the dry mass; n=8.
QM was determined experimentally and used to calculate the volumetric swelling ratio, \( Q_v \) [72]:

\[
Q_v = 1 + \frac{\rho_p}{\rho_s} (Q_M - 1)
\]  \hspace{1cm} (1)

In which \( \rho_p \) is the mass-weighted average density of the dry polymers (PEG = 1.126 g cm\(^{-3}\); HA = 1.229 g cm\(^{-3}\)) and \( \rho_s \) is the density of the solvent (1 g cm\(^{-3}\) for PBS).

Flory-Rehner calculations allow the determination of the crosslink density and mesh size of the gels. The average molecular weight between crosslinks, \( \bar{M}_c \), was calculated using a simplification of the Flory-Rehner equation [73, 74]:

\[
Q_v^{5/3} \cong \frac{\bar{v} \bar{M}_c}{V_1} \left( \frac{1}{2} - \chi \right)
\]  \hspace{1cm} (2)

In this equation, \( \bar{v} \) is the mass-weighted average specific volume of the dry polymers, which is the reciprocal of the density, \( \rho_p \), of the dry polymer. For PEG \( \rho_p = 1.126 \) g cm\(^{-3}\); and for HA \( \rho_p = 1.229 \) g cm\(^{-3}\), and therefore the mass-weighted average specific volumes \( \bar{v} \) of the polymers are 0.888 and 0.814 cm\(^3\) g\(^{-1}\) for PEG and HA respectively. \( \bar{M}_c \) is the average molecular weight between crosslinks, \( V_1 \) is the molar volume of the solvent (18 cm\(^3\) mol\(^{-1}\) for water). The mass-weighted average Flory polymer-solvent interaction parameter, \( \chi \), is based on the values of \( \chi \) for PEG-water [75] and HA-water [Collins/birm=kinshaw APPL POYM SCI XXX], that were 0.426 and 0.473 respectively. Thereafter, the effective crosslink density, \( \nu_e \), was calculated as follows [76]:

\[
\nu_e = \frac{\rho_p}{\bar{M}_c}
\]  \hspace{1cm} (3)
For HA, the following root-mean-square end-to-end distance value was previously reported [76-78]:

\[
\left( \frac{r_0^2}{2n} \right)^{1/2} \approx 2.4 \text{ nm}
\] (4)

Where \( n \) is the number of disaccharide repeat units for HA with a given molecular weight. For HA with a molecular weight (Mn) of ca. 2 MDa, \( n \) is 5305, therefore:

\[
\sqrt{r_0^2} = 0.1748\sqrt{M_n} \text{ (nm)}
\] (5)

Combining equations (4) and (5) and substituting M_c for M_n gives:

\[
\sqrt{r_0^2} = 0.1748\sqrt{M_c} Q_v^{1/3} \text{ (nm)}
\] (6)

The swollen hydrogel mesh size in PBS, \( \xi \), was determined using the following equation [76, 79, 80]:

\[
\xi = Q_v^{1/3} \sqrt{r_0^2} \text{ (nm)}
\] (7)

Approximations were made in the Flory-Rehner calculations, and the values reported (e.g., \( M_c \), \( v_e \), \( \xi \)) are therefore approximations. Nonetheless, these values are useful for making order-of-magnitude comparisons of the biologically relevant features of the gels (such as the mesh size).
**Mechanical Testing**

Compressive tests were performed using an Instron Materials Testing Machine 5543 Series Single Column System (Instron, Norwood, MA) with Bluehill 2 software. Gels were allowed to crosslink in the hydrated state for 24 hours and then allowed to swell for 1 hour in PBS (1 mL). The dimensions of the cylindrical gels (height and diameter) were recorded accurately immediately before compression. Each gel was compressed to 20% of its original height at a rate of 0.05 mm s⁻¹ using a 50 N load cell; n = 6.

Rheological measurements were performed with a Physica MCR 101 Rheometer (Anton Paar, Ashland, VA). A humid atmosphere in the proximity of the gels was assured using wet Kimwipes. Gels were allowed to crosslink in the hydrated state for 24 hours and then allowed to swell for 1 hour in PBS (1 mL). For frequency sweeping tests, storage moduli G' and loss moduli G'' were measured with a constant strain of 2% over a range of frequencies from 10 to 0.1 Hz at 21 °C. For strain sweeping tests, G' and G'' were measured with a constant frequency of 0.1 Hz over a range of strains from 0.1 to 30% at 21 °C; n = 3.

**In Vitro Degradation Studies**

Gel degradation upon exposure to hyaluronidase (10 U mL⁻¹ in PBS) was studied over 25 days. Gels were allowed to crosslink in PBS for 24 hours, swelled in PBS (1 mL) in pre-weighed eppendorf tubes for another 24 hours, and their initial mass recorded. Subsequently, gels were incubated for 24 hours at 37 °C in 1 mL of the hyaluronidase solution. Samples of the supernatant solution (50 µL) were taken and the uronic acid released upon degradation was quantified as described below. After removal of all of the supernatant, the mass of the gel was recorded and fresh hyaluronidase solution (1 mL) was added. The masses of the gels were recorded at specific points in time and the amount of uronic acid released quantified as described below; n = 4.
Uronic Acid Quantification Assay

The quantity of uronic acid released upon degradation of the gels in vitro was assayed using a methodology adapted from the uronic acid carbazole reaction reported by Cesaretti and co-workers [81]. A 50 µL aliquot of the supernatant from the degradation studies was mixed with 200 µL of 25 mM sodium tetraborate in sulfuric acid and heated at 100 °C for 10 minutes. After 15 minutes of cooling, 50 µL of 0.125% carbazole in absolute ethanol was added to each sample and heated once more for 10 minutes. After cooling for 15 minutes, the absorbance at a wavelength of 550 nm was determined using a SpectraMax M3 Multi-Mode Microplate Reader. A standard calibration curve for uronic acid was plotted to define the quantitative relationship between the observed absorbance and the concentration of uronic acid; n = 4.

Cell Culture

Hydrogels were placed in tissue culture plates and sterilized by incubation in 70 % ethanol solution, followed by exposure to UV for 20 minutes. After sterilization, the hydrogels were incubated for 30 minutes under 3 mm of Dulbecco’s Modified Eagle Medium (DMEM), which was exchanged twice after 30 minute intervals. Hydrogels were subsequently incubated for 30 minutes under 3 mm of DMEM supplemented with 10 % fetal bovine serum, 100 U ml⁻¹ penicillin, 100 µg ml⁻¹ streptomycin, 0.25 µg ml⁻¹ amphotericin, 0.1 mM non-essential amino acids, and 1 ng ml⁻¹ basic fibroblast growth factor. Medium was aspirated and replaced prior to HMSC seeding. Cell viability before starting the experiment was determined by the Trypan Blue (Sigma, USA) exclusion method, and the measured viability exceeded 95 % in all cases. HMSCs (passage 2) were seeded on the surface of the gels at 10,000 cells per cm² under 3 mm of medium, and incubated at 37 °C, 95 % humidity, and a CO₂ content of 5 %. After 48 hours the viability of the cells was evaluated using a LIVE/DEAD® Viability/Cytotoxicity Kit for
mammalian cells (Molecular Probes, Eugene, OR). Briefly, the medium was removed and cells on the surface of the gels were incubated with 4 μM ethidium and 2 μM calcein AM in PBS for 15 min at 37°C in the dark. Live cells were stained green because of the cytoplasmic esterase activity, which results in reduction of calcein AM into fluorescent calcein, and dead cells were stained red by ethidium, which enters the cells via damaged cell membranes and becomes integrated into the DNA strands. Fluorescence images of cells were captured using a color CCD camera (Optronics® MagnaFire, Goleta, CA, USA) attached to a fluorescence microscope (IX-70; Olympus America Inc.).
