Abstract
Spatiotemporal variation in climate and weather, allochthonous carbon loads, and autochthonous factors such as lake metabolism (photosynthesis and respiration) interacts to regulate atmospheric CO2 exchange of lakes. Understanding this interplay in diverse basin types at different timescales is required to adequately place lakes into the global carbon cycle and predict CO2 flux through space and time. We analyzed 18 years of data from seven moderately hard lakes in an agricultural prairie landscape in central Canada. We applied generalized additive models and sensitivity analyses to evaluate the roles of metabolic and climatic drivers in regulating CO2 flux at the intra-annual scale. At mean conditions with respect to other predictors, metabolic controls resulted in uptake of atmospheric CO2 when surface waters exhibited moderate primary production but released CO2 only when primary production was very low (<8 μg/L or when dissolved nitrogen was elevated (>2,000 μg/L), implying that respiratory controls offset photosynthetic CO2 uptake under these conditions. Climatically, dry conditions increased the likelihood of in-gassing, likely due to evaporative concentration of base cations and/or reduced allochthonous carbon loads. While more research is required to establish the relative importance of climate and metabolism at other timescales (diel, autumn/winter), we conclude that these hard fresh waters characteristic of continental interiors are mainly affected by metabolic drivers of pCO2 at daily-monthly timescales, are climatically controlled at interannual intervals, and are more likely to in-gas CO2 for a given level of algal abundance than are soft water, boreal ecosystems.

1. Introduction
It is widely accepted that lakes are important nodes that process terrestrial carbon (C) and influence global C fluxes (Cole et al., 2007; Downing et al., 2008; Tranvik et al., 2009). However, improved understanding of regulatory mechanisms, which underlie trends and variability among lentic systems, is needed to improve predictions of how lakes will both contribute and respond to future climate change (Prairie, 2008; Tranvik et al., 2009). In particular, there remains high regional and temporal variation in the mechanisms regulating lake pCO2, despite increasing efforts to synthesize and upscale in-lake CO2 levels and greenhouse gas fluxes. In part, this variability reflects the wide range of analytical methods and study time frames, varying from instantaneous estimates of regional lakes (Duarte et al., 2008; Lapierre & del Giorgio, 2012) to decadal analyses of individual sites (Finlay et al., 2015; Perga et al., 2016). Furthermore, certain lake types (e.g., hardwater and saline) are understudied relative to soft water boreal systems. Variability in the importance of contrasting regulatory mechanisms (e.g., broad-scale climatic drivers versus local metabolic factors) across temporal and spatial scales can obscure the hierarchical relationships among control processes, which in turn limits insights derived from upscaled, ecosystem-level comparisons and global estimates.

Interannual and decadal trends in lake pCO2 are modulated by many interacting variables, primarily acting at the landscape scale through climatic and meteorological drivers. For example, changes in precipitation affect transport of solutes such as dissolved organic (DOC) and inorganic carbon (DIC), which in turn alter lake water CO2 content (Ojala et al., 2011). In the case of organic forms of carbon, higher substrate supply tends to elevate microbial respiration (Ducharme-Riel et al., 2015; Maberly et al., 2013), whereas increased DIC can
either increase or reduce in situ pCO$_2$ in hardwater systems, depending on ambient pH and alternate buffering mechanisms (e.g., Baehr & DeGrandpre, 2004; Knoll et al., 2013). Additionally, landscape-scale variation in irradiance (e.g., cloud cover) or air temperature (O’Reilly et al., 2015) can lead to evaporative concentration of lakes (Pham et al., 2009) and consequent changes in parameters regulating pCO$_2$ (DIC, DOC, nutrients, etc.). For example, in continental Canadian hardwater lakes, interannual variability in both temperature and precipitation has affected pH and CO$_2$ flux via effects of ice-off timing (Finlay et al., 2015), DIC content (Pham et al., 2009), and regional hydrology (Bonsal & Shabbar, 2008; van der Kamp et al., 2008).

Metabolic processes are likely to be paramount in regulating atmospheric exchange of greenhouse gases at scales of hours to days. For example, water column pCO$_2$ typically increases overnight as photosynthesis becomes light-limited and respiration continues (Liu et al., 2016; Raymond et al., 2013). In soft water reservoirs, these diel metabolic patterns can account for ∼30% of total variation in CO$_2$ flux over a summer season (Morales-Pineda et al., 2014). In general, larger diel amplitudes of CO$_2$ content are found as lake productivity increases (Hanson et al., 2003; Morales-Pineda et al., 2014; Shao et al., 2015), suggesting that multiple temporal scales may be needed to evaluate CO$_2$ regulation in productive lakes.

At intermediate timescales, trends in lake pCO$_2$ are likely to be regulated by a combination of metabolic and climatic mechanisms (Morales-Pineda et al., 2014). For example, metabolic controls underlie seasonal trends in dimictic temperate lakes when, in winter, CO$_2$ accumulates under ice (Denfeld et al., 2015), causing springtime efflux of CO$_2$ during ice melt and lake overturn. Reduced pCO$_2$ occurs in summer when the water column is stable and primary production increases, whereas pCO$_2$ increases during fall as respiratory products in the hypolimnion are mixed into surface waters (Alin & Johnson, 2007; Ducharme-Riel et al., 2015; Marcé et al., 2015; Stets et al., 2009). These seasonal patterns can be disrupted by climatic or meteorological events such as passing storms or heat waves (Audet et al., 2017; Klug et al., 2012; Maberly, 1996) or be dampened in polymeric lakes where CO$_2$ exhibits more limited seasonal variation (Jonsson et al., 2003).

While metabolic controls of CO$_2$ also operate at seasonal scales in hardwater lakes (Striegl & Michmerhuizen, 1998), their influence can be overrun by landscape-level controls of solute loading (Anderson et al., 1999; Christensen et al., 2013; Knoll et al., 2013; Marcé et al., 2015; Sobek et al., 2005). For example, lakes with strong groundwater influences can have high allochthonous supplies of DIC and exhibit supersaturation of CO$_2$, particularly in regions close to the groundwater entry points (Stets et al., 2009). On the other hand, the high pH and alkalinity of hardwater lakes also buffers against large fluctuations in pH (Duston et al., 1986; Hanson et al., 2003), leading to smaller amplitudes of both pH and CO$_2$ than exist in soft water lakes. Therefore, especially in polymeric hardwater lakes without strong stratification, hypolimnetic CO$_2$ accumulation should be relatively low and uniform throughout the year, with the net direction of atmospheric CO$_2$ exchange depending on climate effects on solute loading and metabolism. Thus, seasonal patterns of CO$_2$ content in hardwater lakes may contrast sharply from those known from dimictic boreal systems.

Here we use generalized additive models (GAMs) and sensitivity analysis to quantify the effects of climatic and metabolic parameters in regulating intra-annual variability in pCO$_2$ of hardwater lakes in the subhumid Canadian interior. Using biweekly data for 18 years in seven lakes, we sought to determine the following: (1) When and to what extent metabolic factors (photosynthesis and respiration) were regulating lakewater pCO$_2$ and CO$_2$ flux; (2) Whether local meteorology and global climatic factors contribute to intra-annual CO$_2$ flux variability; and (3) How consistent the drivers of CO$_2$ flux were among study lakes that varied more than tenfold in size, productivity, and catchment area. Improved understanding of the relative importance of biotic and abiotic controls of CO$_2$ flux in hardwater lake types is critical to achieving a predictive understanding of the role of freshwater ecosystems in global carbon cycles.

2. Methods
2.1. Study Sites
The seven study sites are situated within the Qu’Appelle River catchment (~52,000 km$^2$) in the northern Great Plains of southern Saskatchewan, Canada (Figure 1). The region has a subhumid continental climate and is hydrologically reliant on water originating from the Rocky Mountains as well as local snowmelt (Bonsal & Shabbar, 2008; Pham et al., 2009). The South Saskatchewan River feeds the Qu’Appelle River system via Lake Diefenbaker reservoir (D). Water flows eastward from the main reservoir through a chain of lakes including Buffalo Pound (B), Pasqua (P), Katepwa (K), and Crooked (C) Lakes. Wascana (W) and Last Mountain (L) Lakes are situated on tributaries that feed into the Qu’Appelle river system upstream of Pasqua Lake.
Figure 1. The seven study sites lie along the Qu'Appelle River (SK, Canada) flowing west to east, with the exception of Wascana (south tributary) and Last Mountain (north tributary).

All lakes receive diffuse nutrient sources from agriculture, with the wastewater treatment plants from the cities of Regina and Moose Jaw acting as point sources of nutrients to Pasqua and eastern basins (Hall et al., 1999). All lakes are dammed to variable extent, and Buffalo Pound and Diefenbaker are actively managed reservoirs. For simplicity, we refer to all sites as lakes.

Median nutrient concentrations are generally elevated (Table 1), including total dissolved nitrogen (TDN) (0.96 mg N/L) and total dissolved phosphorus (106 μg/L), resulting in high algal abundance as chlorophyll a (Chl a; median 16 μg/L) and mesotrophic to hypereutrophic conditions (Finlay et al., 2009; Hall et al., 1999). Compared with saline lakes worldwide (e.g., Duarte et al., 2008), Qu'Appelle lakes have moderate DIC (median = 45 mg/L) and conductivity (median = 1,050 μS/L) but rather high pH (median = 8.8; Figure 2a). DOC concentrations are moderate (median 11.5 mg/L). Temporal variation in many major chemical variables such as pH is highly synchronous across the sites (Figure 2b; Vogt et al., 2011; see Figure A1 for intra-annual variability in variables relating to nutrient status and lake metabolism).

2.2. Long-Term Limnological Sampling
Biweekly limnological sampling of pH, temperature, dissolved oxygen, conductivity, salinity, DIC, DOC, Chl a, TDN, and metabolic bioassay estimates (primary production and respiration) followed methods outlined
Figure 2. (a) Box plots for limnological data used to calculate carbon dioxide flux in the lakes, showing medians, upper and lower quartiles, 1.5 times interquartile ranges, and outliers. (b) Major patterns of annual variation in pH in all lakes, based on a generalized additive model of pH by lake, year, and day of year. Rug: annual means of pH observed over time. DIC = dissolved inorganic carbon.
in Finlay et al. (2009). Briefly, pH was measured at the lake surface, while oxygen, temperature, conductivity, and salinity were recorded at 1-m depth using YSI-85 multiprobe meters (YSI, Inc., Yellow Springs, OH). DIC, DOC, Chl \(a\), TDN, and metabolic bioassay samples used depth-integrated water samples pooled from 2-L Van Dorn sampler casts taken at 0.5-m intervals.

Filtered water (0.45-μm pore size) was used for DIC and DOC analyses using a total carbon analyzer (Shimadzu 500A), while TDN was measured by photocombustion, both following Environment Canada protocols (Environment Canada, 1979). Chl \(a\) was determined trichromatically from particulate organic matter collected on 1.2-μm pore Whatman GF/C glass fiber filters following Jeffrey and Humphrey (1975) and following extraction using 80% acetone: 20% methanol, by volume. The wavelength-specific absorbance was quantified using a Hewlett Packard model 8452A photodiode array spectrophotometer (1996–2004) or an Agilent model 8453 ultraviolet-visible spectrophotometer (2005–2014).

Metabolic estimates of gross primary production, net primary production, and respiration were based on changes in oxygen concentration following incubation of whole water samples in light and dark glass bottles (Finlay et al., 2009). All analyses were run in triplicate using screened (243-μm mesh), depth-integrated water following Howarth and Michaels (2000). Incubations occurred for 24 hr at ambient lake temperature and under a 12-hr light/dark cycle with 450-μmol quanta \(\cdot m^{-2}\cdot s^{-1}\), comparable to that recorded in situ at Secchi depth using a profiling radiometer (Finlay et al., 2009).

Sampling occurred primarily from 1 May to 31 August between the hours of 0900 and 1300, with ~5% of sampling dates occurring earlier in spring or later in autumn. This long-term ecological research program began sampling in 1994, but for reasons related to data availability, we restricted this study to data from either 1996 (most lakes) or 2004 (Pasqua) to 2014, inclusive.

### 2.3. CO₂ Flux Calculation

In the absence of direct measurements of CO₂, we relied on calculated fluxes, which approximate real values particularly well in high-alkalinity lakes (Abril et al., 2015; such as our study sites), where there are strong chemical relationships between pH and dissolved CO₂ (Soumis et al., 2004, \(R^2 = 0.81\)). Calculated values are widely applied in the absence of measurements, particularly when long-term or broad spatial data are being examined (e.g., Duarte et al., 2008; Seekell & Gudasz, 2016).

The procedure for calculating CO₂ fluxes and pCO₂ followed Finlay et al. (2009). Briefly, CO₂ concentrations ([CO₂]) were calculated based on DIC concentrations (depth-integrated samples) and pH (surface), with correction for ionic strength and water temperature measured at 1-m depth (Stumm & Morgan, 1996). Partial pressure of CO₂ (Pa) was estimated using Henry's law constant (Kling et al., 1992), and chemically enhanced CO₂ flux (mmol-m⁻²-d⁻¹) was calculated following Cole et al. (1998):

\[
\text{net daily CO}_2 \text{flux} = \alpha k ([\text{CO}_2_{\text{lake}}] - [\text{CO}_2_{\text{sat}}]),
\]

where in-lake CO₂ concentration for \([\text{CO}_2_{\text{lake}}]\) refers to surface water; saturation levels \([\text{CO}_2_{\text{sat}}]\) refer to equilibrium with the atmosphere; \(\alpha\) is the chemical enhancement of CO₂ flux at high pH (Hoover & Berkshire, 1969), calculated following Wanninkhof and Knox (1996); and \(k\) is piston velocity (cm/hr) following Cole et al. (1998), relating \(k\) to wind speed and temperature (Wanninkhof, 1992).

The effect of an alternative piston velocity was evaluated by including the effect of lake surface area on piston velocity and therefore CO₂ flux in our sensitivity analysis (see section 2.4; equations for \(k\) derived from Table 2, Model B; Vachon & Prairie, 2013. We did not have data to account for wind direction, which would plausibly incur errors in lake area-based estimates of gas transfer for, for example, Katepwa (north-south orientation) versus Pasqua (west-east orientation). Overall, however, the influence of lake area on chemically enhanced flux was subsidiary to \(pH\) and therefore not considered further in this paper.

Complete data for calculating CO₂ flux were available from 1996 for all lakes except Pasqua at which sampling began in 2004. Variables included temperature, pH, conductivity, salinity, DIC, wind speed, air pressure, and atmospheric pCO₂. Observations with any one missing variable were omitted, leaving 991 data points for modeling. Hourly wind speed and air pressure were acquired from publicly available Environment Canada (EC) data (http://climate.weather.gc.ca/) using Regina stations 4016560 and 4016566 (Climate IDs),
which had complete records for the study period. Using one weather station location for all lakes was deemed acceptable as existing records from other weather stations were found highly correlated. Two-week average wind speed was calculated to smooth out brief effects of extreme weather events. Monthly averages of air pressure (Environment Canada) and Mauna Loa atmospheric pCO2 (Earth System Research Laboratory, http://www.esrl.noaa.gov/gmd/ccgg/trends/data.html) were used.

2.4. Statistical Methods
All statistical analyses were performed using R version 3.2.5 (R Development Core Team, 2016), using packages mgcv (Wood, 2011, 2017) and parameterspace exploration (Chalom & de Prado, 2016). R code is available at https://github.com/simpson-lab/jgr-co2-flux.

Our analytical approach follows a few key underlying considerations. Since CO2 flux was estimated from water chemistry and physical variables and not measured directly, we avoided any approach that would circularly include these calculation variables as metabolic or climatic proxy predictors of CO2 flux. Furthermore, we were specifically interested in which of these calculation variables correlate the most with CO2 flux in our study region. In this regard we note that, although the real, rather than estimated, relationship between these variables and CO2 flux is unknown, this step can identify which variable is key to proxy CO2 flux in our region (and conversely, which variables are not). Therefore, we first quantified the influence of the calculation variables on estimated CO2 flux (influence here used in the regression sense of changes in x influencing estimates of y, rather than a directional causal sense). Second, we regressed our metabolic and climatic variables of interest against the variable that accounted for most of this variation. The second step allowed us to use a measured, rather than estimated, response variable, reducing the amount of imprecision in our regression values. We were then able to relate these values back into CO2 flux estimates using the results from the first step, thereby avoiding presenting misleadingly precise results for CO2 flux itself.

2.4.1. Variable Selection
Metabolic variables were selected from various estimates of lake production and respiration to achieve the greatest availability over the data period. In the case of highly correlated variables, we modeled only a single variable, so in our case, respiration (R) was selected over net and gross primary production, whereas TDN was retained over total dissolved phosphorus (at most times at most study sites, N limitation exceeds P limitation; Patoine et al., 2006). Ultimately, five metabolic variables were selected for modeling, including in situ O2 (respiration/photosynthesis), DOC (potential effects on respiration), Chl a (algal biomass or production), R (respiration), and TDN (nutrient availability). Chl a, TDN, and DOC were log10-transformed to approximate a normal error distribution.

To capture the major climatic processes most likely to influence lake CO2 via solute and nutrient loading (hydrological processes and evapotranspiration), we included both broad drivers of intra-annual climate and more local, instantaneous proxies for evaporation-precipitation balance. Variables included the Southern Oscillation Index (SOI) and Pacific Decadal Oscillation (PDO), metrics of climate systems, which strongly influence regional precipitation and temperature patterns, either alone or in combination (Bonsal & Shabbar, 2008; Pham et al., 2009; Shabbar & Yu, 2012). Both indices were included as 3-month averages.

6 months prior to sample collection, to account for the lags between the regions of observation and effect (Pomeroy et al., 2007; Shabbar et al., 2011). Monthly values were obtained from the National Oceanic and Atmospheric Administration (http://www.cpc.noaa.gov/data/indices/soi) and the Joint Institute for the Study of the Atmosphere and Ocean (http://research.jisao.washington.edu/pdo/PDO.latest). Because regional precipitation is highly localized (lake specific; Vogt et al., 2011) and weather stations were not adjacent to our study sites, we did not attempt to use data from weather stations to estimate rainfall. Instead, standardized precipitation evapotranspiration index (SPEI) values for each site (0.5° spatial resolution) were obtained from the Consejo Superior de Investigaciones Científicas (CSIC) Global SPEI database (http://sac.csic.es/spei/database.html; Vicente-Serrano et al., 2016). Index values were calculated using a 2-month memory (autocorrelation) to account for temporal variation in soil drying and hydration.

### 2.4.2. Sensitivity Analysis

Given the absence of direct measurements, we analyzed data to select the best proxy of CO2 in our climatic-metabolic model by simulating the sensitivity of calculated CO2 flux to changes in pH, conductivity, salinity, water temperature, DIC, wind speed, atmospheric pCO2, and local air pressure. A sensitivity analysis was used for this purpose because it shows the magnitude of individual variable contributions to estimate CO2 flux for multiple combinations of variables and values. Further, this method allows us to perform multistep calculations while controlling for underlying data correlations (Chalom & de Prado, 2015).

Differences among lakes in the relative contribution of variables to calculated CO2 flux were tested by comparing an analysis conducted for all lakes combined, with those for each lake individually. Specifically, we used a Latin hypercube sampling approach (Chalom & de Prado, 2015) and generated realistic data variations of all variables for each lake based on their observed variation over the sampling period (n = 500 per simulation). Rank correlations were selected, rather than a linear analysis among variables, to account for potential non-linear relationships between predictors and responses. The output metric (partial rank correlation coefficient: PRCC), for any one variable, controls for the effect of all other variables by reflecting the correlation between the unexplained part of the outcome, given all other variables, and the unexplained part of one variable, given all other variables (i.e., a correlation between residuals).

### 2.4.3. Generalized Additive Models

pH was the strongest correlate with calculated CO2 flux based on sensitivity analysis (see section 3) and, therefore, was carried forward to evaluate the effects of selected metabolic and climatic variables on CO2 flux. Here we applied GAMs, which account for nonlinear relationships between predictors and responses (Hastie & Tibshirani, 1990; Wood, 2017). GAMs also allowed us to include year and lake as random effects to account for between-lake and interannual variations known to be important (Finlay et al., 2009, 2015). The resolutions of all other predictors also link with the resolution of variability they are able to explain: for example, biweekly predictors can explain pH variation at a within-month scale, while monthly predictors can only explain pH variation occurring at a between-month scale. Temporal structure within the climatic-metabolic model was visualized by plotting term contributions to pH against time.

The first model, which evaluated the degree to which lakes differed in their relationship between CO2 and pH, was formulated as follows: for \( y = \) CO2 flux

\[
y = \beta_0 + f_1(pH) + f_2(pH) + \alpha_{lake} + \gamma_{year} + \epsilon.
\]  

(2)

Here the effect of pH was modeled both globally (\( f_1(pH) \)) and by lake (\( f_2(pH) \)), while terms \( \alpha \) and \( \gamma \) were random effects of lake and year, respectively, and \( \epsilon \) was the error term. The global and lake-specific effects of pH were identified via different orders of quadratic penalties on their respective basis expansions. The global function of pH (\( f_1(pH) \)) was subject to the usual second-order penalty, whereby the wiggliness penalty was on the second derivative of a fitted spline. First-order penalties were used for the lake-specific splines so that the penalty applied to departure from a flat or zero function. This approach had the effect of making each \( f_2(pH) \) represent the departure of each lake from the global pH effect. Smoothness parameters for \( f_1 \) and \( f_2 \) were chosen using restricted maximum likelihood selection (Wood, 2011). Lake-specific effects of pH on CO2, \( f_2(pH) \), were only retained when they were assessed to be significantly different from a zero (flat) function. Therefore, lake-specific splines retained reflect regional heterogeneity (objective 3) between the study sites. pH was selected for a combined metabolic and climatic GAM to explore subannual controls of CO2 flux.
Figure 3. Generalized additive model partial effect splines for pH with lake splines significantly different (see section 2.4.3) from the global spline indicated by color/hue and linetype. Dotted lines: means of $y$ and $x$; shaded area: middle 90% of all observations. Rug: data points.

The second model, which quantified the influence of climatic and metabolic variables on pH, followed the principles outlined above for the first model. For $y = \text{pH}$,

$$y = \beta_0 + \sum_{j=1}^{J} \left[ f(x_j) + f_{\text{lake}}(x_j) \right] + f(\text{PDO, SOI}) + \alpha_{\text{lake}} + \gamma_{\text{year}} + \epsilon,$$

where $x_j$ is the $j$th metabolic (TDN, DOC, Chl $a$, and $O_2$) or climatic (SPEI) covariate, $f(\text{PDO and SOI})$ is a 2-D tensor product spline combining the main and interactive effects of PDO and SOI; $\alpha$ and $\gamma$ are random effects of lake and year, and $\epsilon$ is the error term. As above, the unique effects of the $x_j$ for each lake were incorporated through inclusion of separate difference splines for each lake ($f_{\text{lake}}(x_j)$) employing first-order wiggliness penalties. Restricted maximum likelihood smoothness selection was used as described above. Where model terms were marginally significant, likelihood ratio tests were used to determine whether a model including the terms was justifiable.

Preliminary runs suggested that colinearity between DOC and TDN was sufficient to confound results and argued for retaining only one predictor (DOC), based on both internal model Wald tests and Akaike and Bayesian information criteria. However, due to TDN being a significant correlate absent from the final model, the model replacing DOC with TDN is also used in this paper to portray the relationship between TDN and pH.

3. Results

3.1. The Sensitivity of CO$_2$ Flux to Variables Used in Its Calculation

Sensitivity analysis showed that pH explained the greatest amount of variation in CO$_2$ flux (PRCC = −0.96) followed by DIC (PRCC = 0.51) for all lakes (Table 2 and Figure B1). This sequence was also retained in the simulations for individual lakes; however, DIC was more influential in some lakes (B, C, D, and L) than in others (K, P, and W). Overall, the importance of DIC was small (Table 2) and sensitive to which simulation data were used for analysis (not shown).

Generalized additive modeling echoed the results of the sensitivity analysis and showed that pH was the main correlate of CO$_2$ flux (Figure 3). This model explained 97% of deviance in CO$_2$ flux, while the use of DIC as an additional term only explained a further 1% of variation (and an equivalent model with DIC, not pH, explained only 30% of flux variation; not shown).

Lakes were predicted to in-gas atmospheric CO$_2$ above a pH of 8.8, the median pH over the whole data set, while no net atmospheric exchange occurred around pH 8.7. Generally more productive lakes (K, P, and W) were significantly different from less productive sites (B, C, D, and L) based on GAM analysis of the relationship.
between pH and CO₂, primarily at the high and low ends of pH (<10% of all observations). These groups of lake also differed in the extent to which DIC content tended to influence sensitivity analyses (Table 2).

### 3.2. Metabolic and Climatic Regulation of pH

GAM analysis explained 43% of historical deviance in pH, mainly due to climatic and metabolic parameters (Figures 4–6). Significant predictors of pH included Chl $a$ ($p < 0.001$), PDO × SOI ($p < 0.001$), lake + year ($p < 0.001$), oxygen ($p = 0.0108$), DOC ($p = 0.0137$), and SPEI ($p = 0.0122$). The only variable for which individual lake Splines were significant was Chl $a$ (Table 3). In all cases, $R$ was insignificant and removed from the model. The ranges of pH over which the metabolic and climatic variables exerted control were variable, and in decreasing order included PDO × SOI (∼1.5), Chl $a$ (∼1.1), oxygen (∼0.3), DOC (∼0.15), and SPEI (∼0.15), approximately (see uncertainties at the edge of prediction: Figures 4 and 6). Using all measured combinations of our predictors, that is, the empirical data, our model pH predictions encompass a range from 7.8 to 10 (plus/minus errors), which does not capture the full range of observed pH (7 to 10.9; Figures C1 and C2).

Concentrations of Chl $a$ were correlated positively with pH (Figure 4), with low algal abundance (<8 μg/L) occurring when depressed pH correlates with out-gassing of CO₂ when all other predictors were held

at their mean. Results from the two small, shallow lakes (W and B) were significantly different from other basins in that both increases and declines in Chl a had comparatively strong relationships with pH. In general, pH increased with oxygen saturation, with CO₂ in-gassing most likely at supersaturated oxygen concentrations (>9–10 mg/L). CO₂ efflux was only approached at low oxygen concentrations (<5% of all observations, which were lower than ~5 mg/L when all other predictors held at their mean). Finally, DOC was positively correlated with pH, particularly in the range where elevated pH favored influx of CO₂.

In the alternative model where DOC was replaced with TDN, TDN had a slight positive relation with pH up to concentrations of ~1,100 μg N/L above which pH declined consistently (Figure 5). Uncertainties in the effect of TDN on pH were high at both ends of the range due to low observation frequency; however, extremely high values of TDN (>2,000–6,500 μg N/L) cooccurred with pH values that correspond with CO₂ efflux.

Broader-scale climate variables PDO and SOI had stronger relationships with pH than did SPEI (Figure 6). The highest pH values were associated with the most negative SOI and positive PDO (Figures 4a–4c), which typically indicate warm and dry conditions. In contrast variation in SPEI had a limited effect on pH (~0.2 units) and was associated with above mean pH at the low and high end of its range. Low pH was particularly common when PDO was low and wet conditions predominate (Bonsal & Shabbar, 2008). PDO had a more complex multimodal relationship with pH than did SOI, which was more linear (Figures 4b and 4c). For a given PDO, increasing SOI shifted the position of the spline. In general, SOI had a positive relationship with pH except at high PDO when high pH occurred also at low SOI values (Figures 4b and 4c). Overall, the range in climatic index values during the observation period was similar to that recorded during the past century (PDO mostly within −2.2; SOI mostly within −2.5, 2.5; and SPEI mostly within −2.2).

Consistent long-term intra-annual trends were apparent for the metabolic variables Chl a, and oxygen (Figure 7), but not DOC or the climatic variables SPEI and PDO × SOI. Chl a increased in positive effect on pH over the summer in most lakes except during the clearwater phase in June. Below-average pH at low Chl a occurred consistently at the least productive site, Lake Diefenbaker. Oxygen effects in four lakes (C, K, B, and D) were most negative toward the end of the summer.

4. Discussion

Given the importance of climate and ice cover duration in determining annual mean pH and CO₂ flux in these hardwater lakes (Finlay et al., 2015), we sought to determine whether metabolic factors would emerge
Figure 7. Contributions of each predictor to pH summarized over the months of highest data availability, averaged across lakes for weather and climate indices which were homogenous through the study region. Box plots show medians, upper and lower quartiles, 1.5 $\times$ interquartile ranges, and outliers. Shaded area: ±0.05 regions to aid comparison of magnitudes across predictors. PDO = Pacific Decadal Oscillation; SOI = Southern Oscillation Index; DOC = dissolved organic carbon; SPEI = standardized precipitation evapotranspiration index.
as a driving factor at an intra-annual timescale. While we found similar controls also at subannual timescales (high coherence within the region, pH the most significant predictor of CO₂; Table 2 and Figure 3), metabolic controls were important in determining the balance between high likelihoods of influx (pH > 8.8) and efflux (pH < 8.7) of CO₂ (Figure 4). Lake metabolism, as measured using algal abundance (Chl a), was a key parameter controlling whether lakes acted as C sources or sinks within any given year.

4.1. The Role of Lake Metabolism in Directing pH and CO₂ Flux

There was strong evidence for metabolic control of pH and thereby CO₂ flux both at the high and low ends of a gradient of nutrient concentration when either primary production was insufficient to sequester CO₂ or it seemed offset by high levels of inferred respiration. Further, metabolic effects exhibited a strong intra-annual pattern, stressing the importance of short term controls of pH and thereby CO₂ flux in these lakes in calculating the annual CO₂ budget.

Elevated algal abundance increased the likelihood of net CO₂ uptake from the atmosphere. Specifically, we found that CO₂ under average conditions (all other predictors at mean) was in-gassing at moderate to high primary production (Chl a > 8 μg/L), while lower levels of productivity could result in a net heterotrophic state and CO₂ efflux. Such low productivity values were found most frequently in the mesotrophic Lake Diefenbaker, while strongly positive relationships between pH and Chl a occurred often in the most shallow lakes (Wascana, Buffalo Pound; Figure 4). In general, the observed Chl a concentrations needed for net CO₂ release were low relative to those found in other eutrophic lakes where out-gassing may predominate even under the most productive conditions (Chl a >40 μg/L; Huttunen et al., 2003; Reis & Barbosa, 2014), although outgassing was predicted even in our sites at similar algal production provided other predictors were set to values favoring outgassing (e.g., low oxygen and high TDN).

Both Chl a and pH increased through the summer in most lakes suggesting a progressive increase in the importance of metabolic controls. However, these trends were not monotonic, particularly in the more productive lakes. In early summer, the more productive lakes have consistent clearwater periods (Dröscher et al., 2009) caused by strong zooplankton grazing on phytoplankton, thus increasing pCO₂ and subsequently decreasing pH (Figure 7). Conversely, in late summer, the more productive lakes exhibit reduced oxygen concentrations (≤ 5 mg/L) indicative of increased respiration of organic material, which favors release of CO₂ to the atmosphere (Figure 7). More intensive evaluation of fall metabolism is required to establish whether this trend continues through to ice formation in late October or November.

Similar to results of annual mean data (Finlay et al., 2009), rising DOC content tended to cooccur with increasing pH at moderate to high DOC levels (DOC: 5 – 25 mg/L). These patterns are contrary to studies from boreal lakes, which tend to show that DOC mineralization increases pCO₂ and reduces pH (Balmer & Downing, 2011). Although speculative, the observed positive relationship between pH and DOC may reflect recalitrant DOC, which is not respired (Ostapenia et al., 2009), autochthonously derived DOC during high primary production (Søndergaard et al., 2000), and/or a positive correlation between DOC and nutrient influx (Osburn et al., 2011). The latter two are most likely given the positive correlation between TDN and DOC in our study lakes; however, further research is required to distinguish among these explanations.

The unimodal relationship of TDN and pH (peak ∼1,100 μg N/L) suggests that there is a limit to the fertilizing effect of nutrients on primary production and in turn pH. Such a limit may reflect a consistent rise in bacterial decomposition of organic matter along the production gradient, leading to a paramount effect of respiration under highly eutrophic conditions (Hollander & Smith, 2001). In our case, TDN itself may be directly utilized by heterotrophs, as most (>80%) dissolved N in these lakes is in organic forms of TDN not available to autotrophs (Bogard et al., 2012). Consistent with this idea, we note that addition of organic N (as urea) to mesocosm experiments in Wascana Lake increased respiration and decreased pH corresponding with CO₂ efflux (Bogard et al., 2017). Finally, we infer that the negative correlation between high TDN and pH does not reflect a change in the nutrient limitation status of the lakes, as only Diefenbaker and to a lesser extent Buffalo Pound show evidence of P limitation (Quiñones-Rivera et al., 2015; Vogt et al., 2015) and these sites generally exhibit low TDN values relative to other, more definitively N-limited systems (Leavitt et al., 2006; Patoine et al., 2006).

While we observed a predictable positive relationship between pH and O₂ concentration when oxygen was below saturation, the relationship reversed direction when waters were supersaturated with oxygen (Figure 4b). We speculate that there are times when there may be simultaneous supersaturation of oxygen
and CO₂, thereby decoupling the relationships between oxygen and pH, as observed in other hardwater systems where excess allochthonous carbon coincides with high primary production (McDonald et al., 2013; Stets et al., 2009).

4.2. Climatic Regulation of pH

The strength of the relationship between climatic variables and pH was comparable to that of metabolism and pH (Figures 4 and 6), a pattern which suggests that climatic mechanisms may also influence intra-annual variation in regional CO₂ flux. For example, dry and warm conditions (very high PDO and very low SOI) as well as high drought index values were associated with elevated pH and increased concentrations of base cations in these and other lakes (Lake, 2011; Pham et al., 2009). Similarly, this pattern is consistent with findings of Finlay et al. (2015) who demonstrated that spring and summer pH is elevated during years when short duration of ice cover reduces under-ice respiration and favors increased pH in spring and summer. The most likely drivers of climatic effects on pH are increased base cation concentrations due to evaporative concentration (Evans & Prepas, 1996; Pham et al., 2009), elevated residence time (Knoll et al., 2013), reduced allochthonous DIC loads due to longer transit times (Stets et al., 2017), and higher reliance on groundwater contributions (Lake, 2011). However, further research will be required to better refine these possibilities, including spatial studies relating geology, landscape position, external loading, and groundwater supply to seasonality of lake chemistry.

Despite strong and significant results from our modeling exercise, our statistical approach captured only ∼43% of the deviance in pH, leaving a considerable proportion to be accounted for by other factors. Because model residuals were random and normal, they provided little indication of model deficiencies. In principle, model prediction might be improved through distinction of DOC provisdeone via spectrophotometric or compound-specific analyses to better estimate its effect on respiration (Koehler et al., 2012), while quantification of physicochemical processes such as convection and mixing may be important in identifying additional controls of pH, such as seen elsewhere (Liu et al., 2016; Maberly, 1996; Morales-Pineda et al., 2014). Third, the use of more finely resolved taxonomic data (e.g., algal groups) in place of coarse metrics of planktonic metabolism (Chl a, R) may help refine how the importance of biotic controls varies along long limnological gradients (Felip & Catalan, 2000; George & Heaney, 1978; Zhang et al., 2010). Finally, we have not been able to account for alkalinity affecting the buffering capacity and thus the lakes’ responsiveness in pH to changes in metabolic CO₂. However, the lack of overall correlation between pH and metabolic covariates suggests that alkalinity changes should be investigated for their potential contribution to pH and CO₂ flux.

4.3. Regional Coherence and Implications for Upscaling CO₂ Fluxes

Predicting CO₂ fluxes in these hardwater systems was simplified by the fact that DIC concentrations varied little across the lakes and that all lakes behaved similarly with regard to metabolic and physical relationships with pH over broad spatial scales. While the lakes varied substantially in salinity and conductivity (Figure 2), these parameters had relatively low impact on CO₂ fluxes in their respective ranges (Table 2). Conversely, while DIC concentrations are predicted to have substantial effects on atmospheric CO₂ exchange in other lake regions (Cumming et al., 1995; Doctor et al., 2008; Duarte et al., 2008), in our study DIC levels were comparatively low and also correlated weakly and negatively with changes in pH (\( p < 0.001, R^2 = 0.014 \)) which implied an absence of negative effects of high DIC on CO₂ influx at high pH.

We found an unexpectedly strong effect of lake morphology on the role of algal abundance (as Chl a) as a determinant of pH, with the effect of Chl a being much greater in very shallow Buffalo Pound and Wascana lakes (<4-m mean depth) than deeper lakes, particularly at very high pH values (Figure 4). We speculate that shallow lakes are more likely to exhibit whole-lake responses to photic-zone metabolism and may have less vertical structure than even deep polymictic lakes (Zhang et al., 2010; but see George & Heaney, 1978). Fortunately, most prairie lakes are of a similar depth, many being shallow (Last, 1989), suggesting that variation in morphology will not unduly affect efforts to estimate regional CO₂ fluxes (Finlay et al., 2015). Overall, the high level of coherence among basins in terms of high pH and moderate DIC suggests that many lakes will act as CO₂ sinks during much of the summer, provided that they are moderately to highly productive (>8 μg/L Chl a) and are not under extreme (organic) TDN loads.
Metabolic control of CO$_2$ flux in these hardwater lakes does not appear to be as strong as that observed in boreal or soft water regions where microbial metabolism of DOC (Lapierre & del Giorgio, 2012; Sobek et al., 2005) or photosynthesis (Maberly, 1996; Reis & Barbosa, 2014) regulates pCO$_2$, albeit with variable allochthonous contributions of respired or otherwise derived DIC (Bogard & del Giorgio, 2016; Weyhenmeyer et al., 2015). These results fit within the larger matrix of lake types along gradients of DIC, DOC, nutrients, and alkalinity and suggest that moderately hardwater lakes are more likely to capture atmospheric CO$_2$ at a given level of productivity than would dilute lakes (Reis & Barbosa, 2014), those with high DOC loads (Huttunen et al., 2003), or hardwater systems with chronic oversaturation of DIC (Marcé et al., 2015). Further, because such systems often coincide with intensively fertilized agricultural regions, there exists the possibility that many of these systems will fall below the global average estimate of lake CO$_2$ flux (Raymond et al., 2013).

5. Conclusions

Based on advanced time series analysis using GAMs, we found that both metabolic and climatic factors strongly influenced factors related to pH and that variation in DIC was of only secondary importance in affecting CO$_2$ content. Overall, a modest degree of eutrophication was required for high rates of CO$_2$ uptake from the atmosphere and some less productive lakes exhibited a release of CO$_2$ from surface waters. These agricultural areas often exhibit high allochthonous loads of organic carbon and nitrogen, which are likely to fertilize the lake. This increases the likelihood of CO$_2$ influx, but the balance may switch in favor of respiration at extreme nitrogen loads. Overall, climate appeared to have an effect on gas exchange mainly during extremes, such as regional drought, when evaporative concentration of base cations and elevated pH may favor regional influx of CO$_2$ into lakes. These results aid in our ability to understand and predict how future human-mediated changes to nutrient loading and climate change will impact carbon cycling in lakes.

Appendix A: Summary Data for All Lakes

Figure A1. Intra-annual variability expressed as median absolute deviation (i.e., the median of the absolute deviations from the median) of key metabolic and/or nutrient status variables over the LTER period over the months of most frequent observations (May–September). The data are superimposed such that the lakes with the lowest variability appear toward the center of the figure, and lakes with higher variability contain the variability of the more central lakes plus the additional value indicated by the coloring.
Appendix B: Simulated Relationships Between Predictors and CO$_2$
Using Sensitivity Analysis

Figure B1. The relationship between calculated carbon dioxide flux and simulated data sets ($N = 500$) of input variables for sensitivity analysis. DIC = dissolved inorganic carbon.
Appendix C: Model Summaries and Diagnostic Plots

Figure C1. R output for main model diagnostics.
Figure C2. Measured versus predicted pH over time in the study sites, displayed as monthly means over the months of the most frequent observations.
