ABSTRACT: Exfoliation of large-area monolayers is important for fundamental research and technological implementation of transition-metal dichalcogenides. Various techniques have been explored to increase the exfoliation yield, but little is known about the underlying mechanism at the atomic level. Here, we demonstrate gold-assisted mechanical exfoliation of monolayer molybdenum disulfide, up to a centimeter scale. Detailed spectroscopic, microscopic, and first-principles density functional theory analyses reveal that strong van der Waals (vdW) interaction between Au and the topmost MoS2 layer facilitates the exfoliation of monolayers. However, the large-area exfoliation promoted by such strong vdW interaction is only achievable on freshly prepared clean and smooth Au surfaces, while rough surfaces and surfaces exposed to air for more than 15 min result in negligible exfoliation yields. This technique is successfully extended to MoSe2, WS2, WSe2, MoTe2, WTe2, and GaSe. In addition, electrochemical characterization reveals intriguing interactions between monolayer MoS2 and Au. A subnanometer-thick MoS2 monolayer strongly passivates the chemical properties of the underlying Au, and the Au significantly modulates the electronic band structure of the MoS2, turning it from semiconducting to metallic. This could find applications in many areas, including electrochemistry, photovoltaics, and photocatalysis.

KEYWORDS: transition-metal dichalcogenide, MoS2, gold, monolayer, exfoliation, electrochemical, mechanism

Monolayer transition-metal dichalcogenides (TMDs) possess a wide range of extraordinary optoelectronic, chemical, and mechanical properties unattainable in their bulk form.1–3 Many bulk TMDs are semiconductors with an indirect band gap, which transitions to a direct band gap when in monolayer form, rendering them excellent materials for optoelectronics.4–6 A major challenge for large-scale application of TMDs is the competition between material quality and production scalability. For instance, readily scalable liquid-phase exfoliation is tainted by the small size, poor quality, and contamination of the resulting crystals.7 Chemical vapor deposition yields large-area mono-

large, high-quality monolayer TMDCs is therefore crucial for both fundamental research and technology advancement.

Various techniques have been explored to improve the exfoliation yield. Gold is known to have a strong affinity for sulfur, which has been exploited to enhance the exfoliation of monolayer molybdenum disulfide. However, little detail about the underlying mechanism was provided, and the largest MoS$_2$ size was limited to a few hundreds of microns. A comprehensive understanding of the gold-assisted large-area exfoliation at the atomic level is therefore necessary for devising techniques for the mass production of macroscopic TMDC monolayers, whose small lateral size has previously limited research and technological developments.

Here, we present a facile gold-assisted mechanical exfoliation of extraordinarily large monolayer MoS$_2$ up to a centimeter size (Figure 1), and provide detailed investigation on the exfoliation mechanism. Raman spectroscopy, photoluminescence (PL) measurements, X-ray photoelectron spectroscopy (XPS), and scanning transmission electron microscopy (STEM) collectively reveal that the high-yield exfoliation is facilitated by van der Waals (vdW) interaction between the Au surface and the topmost MoS$_2$ layer. This interaction is stronger than the interlayer vdW interactions in bulk MoS$_2$, therefore facilitating the exfoliation of large-area monolayer films. The cleanliness and smoothness of the Au surface are critical for the near-unity yield of monolayer MoS$_2$, which can only be achieved on freshly deposited Au films exposed to air for <6 min. The short air exposure prevents the accumulation of airborne organic contaminants on the Au surface, which otherwise weakens the vdW forces between MoS$_2$ and Au and suppresses the exfoliation. The exfoliation yield also decreases significantly with increasing surface roughness of Au. These findings are confirmed by calculations from the first-principles density functional theory (DFT). The calculated vdW binding energies of several MoS$_2$/Au heterostructures, with varied Au–Mo separations and surface roughness, show excellent agreement with the experiments. We successfully applied this exfoliation technique to a variety of metal chalcogenides, including MoSe$_2$, WS$_2$, WSe$_2$, MoTe$_2$, WTe$_2$, and GaSe (Supporting Figure S1), and found that the monolayer yield is generally near-unity, limited only by the size of the parent bulk crystal.

We further discovered intriguing interactions between monolayer MoS$_2$ and the underlying Au. Electrochemical characterization, using voltammetry and scanning electrochemical microscopy (SECM), reveals that the surface density of electronic states (DOS) of MoS$_2$ is strongly modulated by the underlying Au and, conversely, that the Au substrate is endowed with the chemical properties of MoS$_2$. This is manifested in strong passivation of the Au surface by the physisorbed monolayer MoS$_2$ for inner-sphere electron transfer, while the outer-sphere electron transfer is almost unaffected due to long-range electron tunneling. These intriguing properties bring opportunities for many applications in areas such as electrode modification and energy storage/conversion.

RESULTS

Exfoliation and Characterization of MoS$_2$ on Au.

Figure 1a shows a macroscopic optical image of MoS$_2$ exfoliated on a 7.5 nm-thick Au (111) grown by physical vapor deposition (PVD) on a SiO$_2$/Si wafer with a 1 nm Ti adhesion layer. MoS$_2$ monolayers reach lateral dimensions close to 1 cm, limited only by the size and quality of the parent bulk crystal. The microscopic optical image in Figure 1b reveals good crystal uniformity with occasional breaks likely caused by lattice defects, surface contamination, and mechanical stress during exfoliation. The number of MoS$_2$ layers was unambiguously determined using optical microscopy, Raman spectroscopy, and atomic force microscopy.
The high optical contrast of monolayer MoS₂ allows direct counting of the layers (Figure 1c). The Raman spectra in Figure 1d show the two main vibrational modes, $E_{2g}$ (in-plane) and $A_{1g}$ (out-of-plane), whose intensities increase monotonically with increasing number of MoS₂ layers ($\leq 4L$), as expected. The frequency of both modes blueshifts with the increasing MoS₂ thickness, which is attributed to a stiffening of the vibrations upon layer addition. An anomalous redshift of the $E_{2g}$ mode, due to stacking-induced changes in intralayer bonding, is often observed on insulating substrates. Here we observe a blueshift of the $E_{2g}$ mode, suggesting a strong interaction between MoS₂ and Au, which leads to an efficient charge transfer and screening of the long-range Coulomb interactions between MoS₂ layers. This is also consistent with the large frequency shifts of 8–10 cm⁻¹ between the 1L and 4L MoS₂. AFM topography imaging across a monolayer–bilayer boundary gives a step-height of 9.8 Å (insets in Figure 1e), which is slightly higher than the theoretical thickness of 6.15 Å, but in agreement with the literature. No PL was observed in monolayer MoS₂ on Au (Supporting Figure S2), since it is completely quenched due to the conformal contact between MoS₂ and Au, consistent with previous reports. The occasional observation of PL in monolayer MoS₂ on Au could be caused by an increased physical separation due to polymer residues and airborne contaminants at the MoS₂/Au interface.

Mechanism of the Large-Area Exfoliation. We found that the exfoliation critically depends on the surface condition of Au, governed specifically by the Au roughness and the aging of the Au surface since its deposition under ultrahigh vacuum. The average area yield of exfoliation, expressed as the percentage of Au surface covered with MoS₂ (see Methods), is large (70–80%, predominantly monolayer) on freshly prepared Au, but gradually decreases with the time of Au exposed to air, with an increasingly larger proportion of bulk MoS₂ (Figure 2). After 15 min, almost no crystals are exfoliated (yield <0.5%). This suggests that the adhesion forces between MoS₂ and Au strongly depend on how long the Au surface has aged in air, which we summarize in the following three stages (Figure 2g–i): Initially (1), the adhesion between Au and the first MoS₂ layer is stronger than the interaction between the first MoS₂ layer and the rest of MoS₂, resulting in the predominant exfoliation of monolayer MoS₂. Gradually (2), the MoS₂–Au adhesion weakens and becomes comparable to the interlayer interactions in bulk MoS₂, facilitating more efficient exfoliation of thicker MoS₂ (governed by lattice defects), giving rise to a peak in the bulk yield (Figure 2g–h). In the end (3), the MoS₂–Au adhesion becomes weaker than...
the interlayer interaction in bulk MoS₂, and the exfoliation yield is negligible.

The above phenomenon is caused by the adsorption of organic airborne contaminants, which transform the freshly deposited Au surface from hydrophilic to hydrophobic. This was shown by Smith, who confirmed that while a clean Au surface is hydrophilic, exposure to air (but also prolonged dwell time under vacuum) leads to the build-up of a
submonolayer of carbonaceous contamination, which quickly turns the Au surface hydrophobic.19 This was manifested by an abrupt increase of the water contact angle (WCA) on Au by about 30°−40° within 10 min. Indeed, we found that the WCA on Au exposed to air rapidly increases by 15°−30° in the first 15 min (Supporting Figure S3), following the same trend as the exfoliation yield (Figure 2). The contamination layer increases the separation between MoS2 and Au, weakens the adhesion forces between the two, and consequently reduces the exfoliation yield.

We further found that the yield of monolayer MoS2 notably decreases with increasing thickness of the Au films, as shown in Figure 3a−c for 7.5 and 100 nm-thick Au. The scanning electron microscopy (SEM) images in Figure 3d−e show that the surface of the 7.5 nm Au is smoother than that of the 100 nm Au, which is further quantified by the AFM topography images in Figure 3f−g. The higher surface roughness of the thicker Au film therefore appears to weaken the vdW interactions between Au and MoS2, due to increased physical separation at surface depressions, also supported by theoretical calculations below. The best exfoliation results are achieved on thin Au films of 5−20 nm with root-mean-square (RMS) roughness <1 nm. Despite the polycrystalline nature of the Au films evident from SEM and AFM, the predominant crystal orientation was found to be Au (111) by X-ray diffraction (XRD) measurements (Supporting Figure S4). This is typical for Au PVD films grown on various substrates, using different deposition conditions,20−22 and expected from the lowest energy of the Au (111) surface.23

**The Nature of MoS2−Au Interaction.** The MoS2 interaction with Au was predicted to be of vdW nature due to weak hybridization.24,25 However, few have provided direct experimental evidence of the Au-MoS2 interaction. Here we employed STEM to image the separation between monolayer MoS2 and Au. The left-hand side of the high-angle annular dark-field (HAADF)-STEM image in Figure 4a shows a region of a clean monolayer MoS2/Au interface. The average closest separation between the center of the Mo and Au planes is 5.1 ± 0.3 Å, close to the value of 4.5 Å obtained from theoretical calculations below. This implies a 3.5 Å spacing between the Au and S planes, ∼17% larger than the interlayer vdW spacing in bulk MoS2 (3.0 Å) and ∼59% larger than a covalent Au−S bond (2.2 Å),24,25 confirming that the MoS2−Au interaction is strong vdW rather than covalent in nature. Monolayer MoS2 maintains the spacing due to its conformity with the underlying Au, as seen from the step in the top-right area of Figure 4a. A schematic model of the MoS2/Au heterostructure is shown in Figure 4b.

We also employed XPS to further investigate the interaction between MoS2 and Au. The high-resolution spectra of the Mo 3d and S 2p regions in Figure 4c−d reveal that the binding energies in monolayer MoS2 decrease by ~0.4 eV in
comparison to bulk MoS2. This suggests that there is a significant degree of charge transfer between monolayer MoS2 and Au, consistent with the observed PL quenching. Almost identical shifts (0.4−0.5 eV) were observed in other MoS2−Au systems and explained by the formation of a Schottky barrier at the MoS2/Au interface27 and charge transfer from Au to MoS2, leading to an increase of the electron density at the interface.28,29 Crucially, the lack of changes in the shape and width of the XPS peaks in our work confirms that monolayer MoS2 maintains its chemical identity upon exfoliation (detailed XPS spectra including the peak fittings are shown in Supporting Figure S5).

To further elucidate the interaction between monolayer MoS2 and Au, we performed first-principles atomistic calculations for a range of systems. Figure 5a shows the binding energy ($E_B$, per MoS2 unit cell) for monolayer MoS2 on different systems: pristine Au (111) surface, Au surface with n missing Au rows, and m-layer MoS2. The calculations suggest $E_B = -0.41$ eV for monolayer MoS2 on pristine Au (Figure 5a), which is stronger than the binding between monolayer MoS2 and bulk MoS2 ($E_B = -0.34$ eV for $m \geq 5$), supporting the predominant exfoliation of monolayers, in agreement with our earlier interpretation and other theoretical calculations.25,31 The binding energy between Au and MoS2 rapidly decreases with increasing Au−MoS2 separation (Figure 5b), explaining why a submonolayer contamination significantly inhibits the exfoliation.

Introduction of a small number of surface Au vacancies or adatoms is found to have negligible effects on the binding energy ($-0.42$ eV). Conversely, when a large vacancy in the form of n missing surface rows is introduced to the Au surface, the binding energy changes significantly. As shown in Figure 5a, the $E_B$ is initially high for $n = 1$ but decreases to reach a similar magnitude to that of pristine Au for $n = 3$. The increased number of active sites with large amount of dangling bonds and charge density at the Au surface initially leads to a stronger Au−S interaction, as seen for $n \leq 3$. For $n = 3$, the comparably poorer conformity of MoS2 to Au weakens this interaction, which becomes comparable to that of bulk MoS2 for $n = 5$ and 6. These calculations are consistent with the observation that the smooth, thin Au can produce large-area exfoliation, while the rougher, thicker Au cannot. This reinforces our conclusion that the surface quality of Au is critical for the success of large-area exfoliation.

The most striking difference occurs in the electronic structure of MoS2. The semiconducting character of free-standing MoS2 changes to metallic in the monolayer MoS2/Au heterostructure (Figure 5c). Indeed, the Bader charge analysis indicates a system-dependent electron transfer from Au to the monolayer MoS2 (Supporting Figure S6). The resulting increase of the DOS at the Fermi level ($E_F$) has a direct impact on the electrochemical behavior discussed below. These states, which originate mainly from S 3$p$−$p$ orbitals and Mo 4$d$ orbitals, reside at the MoS2/Au interface (Figure 5d−e).

### Electrochemical Characterization of the MoS2−Au Heterostructure

The large-area monolayer MoS2 on Au is an excellent platform for investigations previously limited by...
the small lateral crystal size. Figure 6 shows the electrochemical characterization of three macroscopic (~0.5 mm²) surfaces: bare Au (gold), monolayer MoS₂/Au (red), and bulk MoS₂ (gray). The kinetics of the reduction/oxidation of [Ru(NH₃)₆]₃⁺/²⁺ and [Fe(CN)₆]₃⁻/⁴⁻ used as redox mediators, quantified by the heterogeneous electron-transfer rate constant (k₉), vary greatly on these surfaces, as illustrated by the voltammograms in Figure 6a–b. Au exhibits the fastest, reversible kinetics for both mediators (k₉ > 1 cm s⁻¹), expected due to their fast self-exchange rates and the high DOS of Au. The k₉ values on bulk MoS₂ are ~4 × 10⁻⁴ cm s⁻¹ and <10⁻⁷ cm s⁻¹ for [Ru(NH₃)₆]₃⁺/²⁺ and [Fe(CN)₆]₃⁻/⁴⁻, respectively, in agreement with previous work. The kinetics of [Ru(NH₃)₆]₃⁺/²⁺, which is thought to be an outer-sphere mediator only sensitive to the surface DOS, are reversible on monolayer MoS₂/Au and similar to that of bare Au (Figure 6a), indicating strong electronic coupling and charge transfer between MoS₂ and Au, in agreement with our results above. The SECM imaging of the [Ru(NH₃)₆]₃⁺/²⁺ redox activity of MoS₂ on Au (Figure 6c–e) shows a clear correlation with the corresponding optical image (Figure 6f). As the number of MoS₂ layers decreases, the normalized current (I/I₀) increases, indicating a transition from the semiconducting multilayer MoS₂ to the metallic monolayer MoS₂/Au in agreement with the predicted increase in DOS (Figure 5f), with the highest current observed for the bare Au. In contrast, the kinetics of [Fe(CN)₆]₃⁻/⁴⁻ on monolayer MoS₂/Au slows down by 6 orders of magnitude to ~1 × 10⁻⁴ cm s⁻¹ within the quasi-reversible regime (Figure 6b). The strong suppression of the kinetics of [Fe(CN)₆]₃⁻/⁴⁻, which is an inner-sphere mediator interacting strongly with the electrode surface, indicates that the Au surface is strongly passivated by the MoS₂ monolayer. In addition, the open circuit potential in 1 M KCl was found to be the same for monolayer MoS₂/Au and bulk MoS₂ (0.000 V), but considerably different for Au (0.034 V). No dependence on illumination was observed for monolayer MoS₂/Au, as expected. These results suggest that monolayer MoS₂/Au is chemically similar to MoS₂ but has an increased DOS acquired from the underlying Au. In other words, monolayer MoS₂/Au is thermodynamically closer to bulk MoS₂ but kinetically closer to Au. These characteristics could be effectively used to discriminate between the outer- and inner-sphere electron-transfer mechanisms. A similar concept of electronic modulation was recently demonstrated for graphene on Au.

Capacitance measurements in 1 M KCl also reveal significant differences between the three surfaces (Figure 6g). The interfacial (measured) capacitance Cₑₑₑ is a sum of two capacitances in series: Cₑₑₑ = Cₛₑᵦ + Cₑᵦₑ, where Cₛₑ and Cₑᵦₑ are the space charge and electrical double-layer capacitances at the electrode/liquid interface. The interfacial capacitance Cₑₑₑ is 34 μF cm⁻² for bare Au and is equal to Cₑᵦₑ due to the efficient Thomas-Fermi screening in metals. In semiconductors Cₛₑ ≪ Cₑᵦₑ. An intermediate Cₑₑₑ = 3 μF cm⁻² in monolayer MoS₂/Au is mostly dominated by Cₛₑ (Cₑₑₑ ≈ 0.9 Cₛₑ calculated using the Cₑᵦₑ determined for Au). The shapes of the voltammograms in Figure 6g reflect the differing electronic band structures of the three different surfaces. The metallic Au behaves as a typical pseudocapacitor with a redox (faradaic) activity superimposed over the double-layer charging at high potentials. The response of bulk MoS₂ is typical for an n-type semiconductor, with the higher currents at low potentials corresponding to the charge carrier accumulation regime. Surprisingly, monolayer MoS₂/Au exhibits a rectangular-shaped voltammogram, indicating a purely capacitive (nonfaradaic) response, which originates solely from the double-layer charging. Such potential-independent capacitance response, which is typical of an electrochemical supercapacitor, is significantly different from the responses of bulk MoS₂ and bare Au. This suggests that monolayer MoS₂/Au system (and potentially many other TMDCs/Au) could provide an interesting platform for the design of supercapacitors and other devices for electrochemistry, photocatalysis, and energy storage/conversion.

CONCLUSIONS

We present a facile gold-assisted mechanical exfoliation of extraordinarily large monolayer MoS₂ up to a centimeter-scale, limited mainly by the parent bulk crystal size. We carried out detailed spectroscopic and microscopic characterizations together with first-principles DFT calculations to provide an atomic-level understanding of the exfoliation mechanism. The large-area exfoliation is found to be facilitated by strong vdW interaction between Au and the topmost layer of MoS₂, which critically depends on the cleanliness and smoothness of the Au surface. Near-unity yield of monolayer MoS₂ is achieved on freshly grown thin Au films (5–20 nm) with RMS roughness <1 nm and exposure time for <6 min. The yield becomes negligible after 15 min of exposure due to the accumulation of airborne contamination on Au. Such previously unknown stringent experimental conditions have important consequences for the development of large-area exfoliation and growth techniques. We have successfully extended the technique to MoSe₂, WS₂, WSe₂, MoTe₂, and GaSe. Electrochemical characterization reveals that the surface DOS of monolayer MoS₂ is strongly modulated by the underlying Au, turning it from semiconducting to metallic. Conversely, the subnanometer-thick monolayer MoS₂ strongly passesivate the chemistry of the underlying Au electrode, but does not prevent charge transfer from solution to Au. Our work sheds light on the mechanism of gold-assisted exfoliation, provides important guidance for the production of macroscopic TMDC monolayers, and has important implications for many research areas, such as electrode modification, photovoltaics, and photocatalysis.

METHODS

Materials Preparation. PVD films were prepared with a DC magnetron sputtering system (Kurt J. Lesker CMS-A) using targets (>99.99%) from Testbourne Ltd. (TI) and Birmingham Metal Ltd. (Au). The SiO₂/Si wafers (IDB Technologies Ltd.) were cleaned in acetone and isopropanol and blow-dried before placing in a load-lock, evacuated to ~10⁻⁷ Torr by a turbomolecular pump (Shimadzu TMP-303LMM) backed by a mechanical pump (Aixzen ACP 15). They were then transferred to the deposition chamber, evacuated to ~10⁻⁹ Torr using a cryopump (Brooks CTI-Cryogenics 10F). All the pumps were oil-free, and the residual gas environment was continuously monitored by mass spectrometry prior to the sputtering. Depositions were done at room temperature under a 5 SCCM Ar flow at partial pressure of 10⁻⁵ Torr. A Ti adhesion layer was deposited at 15° incidence at a rate of 0.5 Å s⁻¹ before the Au deposition. The Au layer was deposited at a 33° incidence at a rate of 1.5 Å s⁻¹. Both targets were presputtered prior to the deposition. All metal chalcogenides were exfoliated from bulk crystals (Manchester Nanomaterials Ltd.) directly onto the Au substrates using the “scotch-tape” method reported elsewhere, applying a downward pressure, rather than lateral rubbing. The crystals were exfoliated, and therefore exposed to air, immediately prior to the contact with Au (<5 s) in order to
minimize the airborne contamination of their surface. Bulk crystals were either natural (molybdenite) or synthesized by chemical vapor transport (MoSe2, MoTe2, WS2, WSe2, WTe2, and GaSe). The exfoliation and subsequent characterization (except the vacuum techniques) were performed at 20–23 °C and 50–70% relative humidity.

Microscopy, Spectroscopy, Reflectivity, and Diffraction Characterization. Macroscopic optical images were taken using a Canon PowerShot A720 IS digital camera. Microscopic optical images were taken using a BXS1 microscope (Olympus Corp) with an Infinity2-2 CCD camera and Infinity Capture 6.2 software (Lumenera Corp). The exfoliation yield should ideally be calculated as the ratio between the area of the exfoliated film and the contact area surface of parent MoS2 crystals. However, as the size of the parent crystals and their surface defect and impurity densities vary for different exfoliations, such approach is impractical. To circumvent this uncertainty, we used a constant sampling area (rather than the actual parent crystal size) for each yield comparison. For Figure 2, identical square areas of 0.5 × 0.5 cm2 were chosen at three different locations on each sample using Fiji/ImageJ software (v.2.0) to maximize the area of exfoliated MoS2 films inside the square boxes. The exfoliation yield (Y) was then calculated as Y (%) = 100% × 100%, where AY is the area of exfoliated MoS2 inside each of the square box and A0 is the sampled area. The results are shown in Figure 2g. A sampling area of 110 × 100 μm2 was used to calculate the roughness-dependent exfoliation yields in Figure 3. Such a method allows meaningful quantitative comparison of the yield dependence on the surface condition of Au and provides a quantitative assessment of the capability of the technique. 32 or 633 nm lasers of 1 mW power focused through a 100X MPLAN N objective (Olympus Corp) to ∼1 μm spot size were used for Raman spectroscopy and PL measurements, collected by a Jobin Yvon HR640 Raman spectrometer and Andor MCD 2.6 software. AFM measurements were performed with a Digital Instruments Veeco Dimension 300 AFM with 30 nm Si-SPM tips (Nanosensors) in tapping mode. The contact angle measurements were carried out using a Dino-Lite Edge AM7115MZTL Digital microscope and in-house rotating-state contact angle measurements, collected by a Jobin Yvon HR640 Raman spectrometer, taken using a D8 Discover diffractometer (Bruker Inc.), were used to determine the thickness and crystallographic orientation of Au, respectively. XPS was performed using a nonmonochromatic Mg Kα source, collecting the photoelectrons at glancing incidence from the surface normal, from an area of ~0.8 cm2. The spectrometer energy analyzer work function was calibrated using an Ag standard. Tougaard baseline subtraction and normalization to the maximum intensity were applied to all spectra. STEM samples were prepared in a FEI Strata 400 focused ion beam using a standard cross-section fabrication procedure. 38 STEM and electron energy loss spectroscopy (EELS) imaging were performed using a NION UltraSTEM operated at 100 keV.

Computational Methods. First-principles ab initio calculations were carried out with the Vienna ab initio simulation package. 7 The generalized gradient approximation along with the Tkatchenko–Schlöffel method were used to correct the energy due to dispersion interactions. 40,41 This was used along with a 345 eV plane-wave cutoff. The projector augmented wave pseudopotentials were utilized to model the bonding environment between atoms. 42,43 Energy convergence for the electronic and ionic minimizations was set at 1 × 10−5 and 1 × 10−4 eV, respectively. Au (111) and monolayer MoS2 unit cells were relaxed with a 12 × 12 × 6 and 12 × 12 × 1 G-centered k-grid, respectively. From this an 8 × 8 × 4 Au surface was created as well as a 7 × 7 × 1 MoS2 supercell. This resulted in ~1.0% lattice mismatch, which was applied to the Au surface to avoid spurious variation on the strain sensitive MoS2 energetics. The bottom two Au layers were fixed as bulk, while the top two Au layers, representing the surface, were allowed to relax. After the introduction of defects, the Au surface was allowed to relax further. The MoS2 supercell was then placed on top of the Au surface, and the MoS2/Au heterostructure was allowed to relax once again. Binding energies of 1L MoS2 on n-

layer MoS2 were calculated as E = E_{\text{MoS}_2} − E_{\text{Au}} − E_{\text{fl}}, where E_{\text{MoS}_2}^{\text{m+1}}, E_{\text{fl}}, and E_{\text{fl}} are the total energies of (m + 1), m-, and 1-layer MoS2, respectively. Binding energies of 1L MoS2 on Au systems were calculated as E = E_{\text{Li}+\text{Au}} − E_{\text{Au}} − E_{\text{fl}}, where E_{\text{fl}}^{\text{1L}}, E_{\text{Au}}, and E_{\text{fl}} are the total energies of 1L MoS2 on Au and the Au slab, respectively.

Electrochemical Measurements. All electrochemical measurements were performed using a CHI920D potentiostat (CH Instruments, Inc.). The electrochemical setup is schematically shown in Supporting Figure S7. The k2 values were estimated from the peak-to-peak separation in the voltammograms (10–400 mV s−1). This was done using the Nicholson method and the Klinger–Koch method in the reversible-quasi reversible and irreversible regime, respectively, following the methodology reported elsewhere (eqs (1) and (2) in ref 44, respectively). Diffusion coefficients of 7.4 (5.3) × 10−6 cm2 s−1 and 7.7 (6.2) × 10−6 cm2 s−1 for the oxidized (reduced) forms of [Ru(NH3)6]3+/2+ and [Fe(CN)6]3−/4−, respectively, were determined from voltammetry at polished 2 mm diameter Pt disk using the Randles–Ševčik equation. 35 The interfacial capacitance (C_	ext{int}) was calculated by integrating the current over the potential range as described elsewhere and averaged for scan rates between 10−50 V s−1. 36 The reference potential used here (Ag/AgCl in 1 M KCl) is +0.232 V on the standard hydrogen electrode scale, taking the activity coefficient of Cl− into account. 40 SECM was obtained using a 1 μm diameter Pt ultramicroelectrode probe with a glass radius of ~25 μm (Heka), operated in feedback mode at a working distance of ca. 1 μm. The probe potential was set to reduce/oxidize [Ru(NH3)6]3+/2+ under diffusion control, while the substrate was unbiased. The probe current (I) measured near the surface was normalized to the current in bulk solution (I0).

Royal Academy of Engineering under the research Chairs and Senior Research Fellowships Scheme, CCMR (NSF-DMR-1719875), PARADIM (NSF-DMR-1539918), DOE CSGF (DE-FG02-97ER25308), NSF-CHE-1708025, and the Alfred P. Sloan Foundation. E.J.G.S. acknowledges the use of computational resources from the UK high-performance computing service (ARCHER) for which access was obtained via the UKCP consortium (EPSRC grant ref EP/K013564/1), the UK Materials and Molecular Modelling Hub for access to THOMAS supercluster, which is partially funded by EPSRC (EP/P020194/1). The Queen’s Fellow Award (M8407MPH), the Enabling Fund (A5047TSL), and the Department for the Economy (USI 097) are also acknowledged.
