Frequency Diverse Array (FDA) OFDM Transmitters: Consider an N-by-1 FDA with uniform array element spacing $d$ and uniform frequency increment $\Delta f$ across the array aperture, the signal $S$ received at a location $(R_i, \theta)$ in free space can be expressed as:

$$S = \sum_{n=1}^{N} A_n e^{-j(2\pi f_i R_i/n + kd)}$$

where $f_i$ is the RF carrier frequency of the signal applied to the $n$th array element, $f_0 = f_i + (n-1)\Delta f$. $A_n$ is a complex number representing information data for transmission. $R_n = R_i - (n-1)d \cos \theta$ is the receiver displacement relative to the $n$th array element. The first element is set as reference, $\theta$ is the azimuth angle with boresight along $90^\circ$, and $\delta$ denotes the speed of light. Phase $\phi_n$ is the initial phase of the $n$th RF carrier. Assuming that the receiver node is located in the far-field region, then the path loss from each array element is approximately identical, and is therefore omitted in (1).

Rewriting (1) as (3),

$$S = \sum_{n=1}^{N} A_n e^{j\phi_n} e^{j2\pi f_i R_n/n} e^{-j2\pi f_0} e^{-j2\pi (n-1)\delta}$$

In order to allow information $A_n$ to be extracted from $S$, the $N$ summation terms have to be separated and the four exponential coefficients removed. This is performed as follows.

At the receiver side frequency down-conversion by multiplying by a RF carrier $e^{j2\pi f_0}$ eliminates the coefficient $e^{-j2\pi f_0}$ in (3). The separation of the $N$ summation terms and the removal of $e^{-j2\pi (n-1)\delta}$ can be concurrently achieved with the help of the orthogonality property of the function sets $e^{-j\beta x}$ for different integer $p$ within any $2\pi$ range. Namely,

$$\frac{1}{2\pi} \int_{-\pi}^{\pi} e^{-j\beta x} e^{j\alpha x} dx = \begin{cases} 0 & \text{if } p, q \in \mathbb{Z}, \forall i \in N, p \neq q \\ 1 & \text{if } p, q \in \mathbb{Z}, \forall i \in N, p = q \end{cases}$$

As a consequence by comparison the time $t$ in (3) has to be confined within a range between $a/\Delta f$ and $(a+1)/\Delta f$, $a$ can be any positive real number. In other words the symbol duration $\Delta T$ is required to take values of $i/\Delta f$ in order for data recovery to occur. Fig. 1 depicts the frequency spectrum of each carrier in signal $S$ within $\Delta T$ for $i = 1$ and $N = 5$. This is calculated by performing a Fourier transform after multiplying (3) by the rectangular window function $rect(t)$, defined in (5),

$$rect(t) = \begin{cases} 1 & t \in [a/\Delta f, (a+1)/\Delta f] \\ 0 & \text{others} \end{cases}$$

Here we have assumed that $A_n$ for each $n$ have the same absolute value $|A|$. It is observed that the carriers are orthogonal to each other in frequency domain at their respective centre frequency. Inspection of the signal spectrum in Fig.1 shows that by confining the symbol time period to $1/\Delta f$ the detected signals are OFDM modulated signals with each sub-carrier being transmitted separately via each FDA element.

**Fig. 1** Frequency spectrum of each carrier in received signal $S$ in (3) upon confining the symbol time period $\Delta T$ as $1/\Delta f$. $N = 5$ for this example.

**FDA OFDM Transmitter for Secure Wireless Communication:**

In conventional OFDM systems each modulated symbol weighted sub-carrier is combined before being routed to the antenna array for transmission. For this scenario (6) gives the detected signals $S'$ along direction $\theta$ in free space,

$$S' = AF(\theta) \cdot S = \sum_{n=1}^{N} A_n e^{j2\pi f_i R_n/n} e^{-j2\pi (n-1)\delta}$$

From (6) it can be concluded that the modulated OFDM signal waveforms are preserved along all $\theta$ with the ability to recover the transmitted information being determined by signal to noise ratios (SNRs) governed by the array factor $AF(\theta)$, distance $R$ from the transmitter, and channel noise.

This characteristic, however, does not hold for the proposed FDA OFDM transmitter. By comparing (3) and (6) it can be seen that the FDA OFDM transmitter permits the possibility for manipulation of the phase of each sub-carrier in the OFDM signals by choosing the sub-carrier initial phase $\phi_n$ and selecting which array elements radiate each sub-carrier, i.e., $\phi_n$ and $2\pi f_0 R_n/c$ in (3). Thus this provides an extra degree of freedom unavailable to the conventional OFDM transmitters. The result of this is the projection of different signal waveforms along different directions since $R_n$ is a function of $\theta$, (2).

The ability for signal waveform manipulation that the FDA OFDM transmitter possesses can be exploited by setting the summation of $\phi_n$ and $2\pi f_0 R_n/c$ be a constant $\Phi$ for each $n$ along an a-priori selected communication direction $\theta_0$ for the purpose of securing a wireless communication along that direction. $\Phi$ can be any real number, and it acts to describe the rotation of symbol constellation diagram in IQ space for each sub-carrier. This rotation can be fully compensated, only, by receivers located along $\theta_0$, $f_0$ is fixed for the $n$th sub-carrier. $R_n$ is a function of both $n$ and communication direction $\theta$, (2). Select $R_n$ according to (2) for the specified array element and given direction $\theta_0$ and solve for $\phi_n$. Under this condition

$$S'_c(\theta_0) = \sum_{n=1}^{N} A_n e^{j2\pi f_i R_n/n} e^{-j2\pi (n-1)\delta}$$

For Fig. 1
which indicates that the OFDM signal waveforms are well preserved along $\theta$. On the other hand, signal waveforms are scrambled at all directions other than $\theta$ since the summations of $\phi_n$ and $2\pi f R_e/c$ are no longer a constant for each $n$ and the OFDM time waveform signature becomes distorted.

**Simulation Results:** In order to validate the superiority of the proposed FDA OFDM transmitter types over the conventional OFDM transmit architecture, the bit error rate (BER) spatial distributions in free space in the different systems are simulated under the following prerequisites:

- In IEEE 802.11 OFDM systems [9], used here to facilitate further discussion in this paper, block type training sequences are adopted where each sub-carrier is appended with an identical training preamble, consisting of both short and long training symbols. The preamble is utilized to determine, for each separate OFDM sub-carrier, where the information data begins and what the phase reference of each sub-carrier is, i.e., $\phi_n + 2\pi f R_e/c$ along all directions if the mappings between array elements and sub-carriers are fixed in one data packet. As a consequence, in order to exert uncorrected distortion at all spatial directions other than $\theta$, the mappings need to be updated dynamically on a per transmitted symbol basis while satisfying $\phi_n + 2\pi f R_e/c = \Phi$ along desired $\theta$. This scheme not only disconnects the training sequences and their corresponding sub-carrier data, but also scrambles the training preambles themselves, leaving little chance of eavesdropper data interception along directions other than that pre-specified.

- IEEE 802.11 OFDM (20 MHz channel spacing $B$) physical-layer specification [9] is adopted. No data coding and interleaving are performed. The OFDM signals contain 64 subcarriers, of which 52, 48 for data and 4 for pilot, are used for transmission. $f_t = 2.404$ GHz (channel 1 at 2.4 GHz band), and $\Delta f = B/64 = 312.5$ kHz.

- A 9-by-1 isotropic antenna element array with half-wavelength spacing with respect to $f_t$ is used. Since $N = 9 < 52$, it is inevitable that several sub-carriers are mapped onto a same array element for transmission. The mapping is performed by random assignment, i.e., for this example each transmitted OFDM symbol each of the 52 sub-carriers has a 1/9 chance to be assigned to random of the 9 array elements. This arrangement, compared with the conventional OFDM systems wherein all sub-carriers are combined, reduces the peak-to-average power ratio (PAPR) of signals at the transmitter side, which leads to increased power efficiency of the transmit power amplifiers.

- Each OFDM packet consisting of around 800 random data bits is appended with standard IEEE 802.11 OFDM preambles. 10 packets are used for each BER simulation, which allows BER down to $10^{-5}$ to be calculated.

- For fair comparison in terms of secrecy performance the signal to noise ratios (SNRs) detected by receivers located along pre-selected directions in both systems are normalized to be identical. AWGN contribution is identical in all directions. It is also assumed that legitimate receivers and eavesdropper receivers are located at a same distance away from the transmitter, (the case of different distances is equivalent to different receive SNRs).

In Fig. 2 the BER simulation results obtained for 60º and 90º pre-defined communication directions respectively are depicted, other directions could have equally been selected. Both low and high SNR values are chosen for each case to facilitate BER main beam and sidelobe comparison in FDA and conventional OFDM systems. The sample results in Fig. 2 validate that the OFDM signal waveforms are well preserved only along pre-selected directions, i.e., in the example shown here for Gray-coded QPSK and 16QAM modulations respectively BERs detected along the directions of 60º or 90º in both conventional and FDA OFDM systems are approximately the same and follow the BER-SNR relationships stated in [10]. We can also conclude that FDA OFDM systems are able to greatly confine BER spatial spread around the selected communication directions and suppress BER sidelobes, especially under high SNR scenarios. This secrecy enhancement is off course obtained at the cost of radiating more energy into space since the system provides no beam-forming gain, see (7). This can be partially alleviated by only applying the FDA OFDM technique onto the appended training preamble in each data packet, and enabling beam-forming functionality for the resultant information data, i.e., hybridizing FDA and conventional OFDM transmitters.

**Conclusion:** An FDA inspired array-level OFDM transmitter was proposed that has the ability to secure wireless communication in free space at the physical-layer along a prescribed direction. The approach was validated via BER simulations using the IEEE 802.11 OFDM physical-layer specification. Experimental verification of the system suggested here will be the subject of later work. The FDA OFDM transmitter concept introduced in this paper could be useful in applications where enhanced security through physical-layer augmentation would add operational benefit.
