ABSTRACT

Context. The Na X-ray lines between 10.9 and 11.2 Å have attracted little attention but are of interest since they enable an estimate of the coronal abundance of Na to be made. This is of great interest in the continuing debate on the nature of the FIP (first ionization potential) effect.

Aims. Observations of the Na lines with the Solar Maximum Mission Flat Crystal Spectrometer and a rocket-borne X-ray spectrometer are used to measure the Na/Ne abundance ratio, i.e. the ratio of an element with very low FIP to one with high FIP.

Methods. New atomic data are used to generate synthetic spectra which are compared with the observations, with temperature and the Na/Ne abundance ratio as free parameters.

Results. Temperature estimates from the observations indicate that the line emission is principally from non-flaring active regions, and that the Na/Ne abundance ratio is 0.07 ± 50%.

Conclusions. The Na/Ne abundance ratio is close to a coronal value for which the abundances of low-FIP elements (FIP < 10 eV) are enhanced by a factor of 3 to 4 over those found in the photosphere. For low-temperature (T_e < 1.5 MK) spectra, the presence of Fe XVII lines requires that either a higher-temperature component is present or a revision of ionization or recombination rates is needed.

Key words. line: identification – Sun: abundances – Sun: corona – Sun: flares – Sun: X-rays, gamma rays

1. Introduction

Sodium has few prominent or unblended emission lines in the ultraviolet and X-ray spectra emitted by solar coronal plasmas. Hence determinations of its abundance relative to other elements rely on measurements of emission line fluxes that are either weak or in crowded spectral regions. Yet its abundance is important for discussions of the so-called FIP effect, whereby coronal element abundances differ from corresponding photospheric values depending on whether their first ionization potential (FIP) is greater or less than about 10 eV (Meyer 1985; Feldman et al. 1992a). This is because the FIP of Na is only 5.14 eV, less than any other element common in the Sun apart from potassium, which has an FIP of 4.34 eV. Determinations of the coronal abundance of either Na or K can therefore probe the possibility that elements with small FIP are enhanced by amounts that depend on the magnitude of the FIP, as is suggested by the electric current model of Hénoux & Somov (1997) to explain the FIP effect. Observational evidence for this has been provided by Feldman (1993), and to some extent by observations of He-like K X-ray lines seen in numerous flares and non-flare periods between 2002 and 2005 with the RESIK spectrometer (Sylwester et al. 2010). Coronal sodium emission lines include the Li-like Na (Na Ix) resonance lines 1s^22s 2S_1/2−1s^22p 2P_1/2, 3P_1/2 in the extreme ultraviolet, at 681.7 Å and 694.3 Å, and the He-like Na (Na X) line 1s2s^2 3S_1−1s2p 1P_1 at 1111.76 Å seen in SOHO SUMER spectra (Curt et al. 2000, 2001), and resonance lines of H-like (Na XI) and He-like Na (Na X) in the soft X-ray range. X-ray observations of the Na X and Na XI X-ray emission lines should in principle be easier than for the equivalent potassium lines as the photospheric abundance of Na is higher by a factor of 16 than K (Asplund et al. 2009), but nevertheless observations remain scarce. The Na XI Ly-α and Ly-β lines are at 10.02 Å and 8.46 Å respectively, and the Na X 1s^2−1s2l (l = s, p) lines are near 11 Å. The Ly-β line was observed by Walker et al. (1974) with crystal spectrometers on the OVI-17 spacecraft, and the Na X lines with rocket-borne crystal spectrometers by Parkinson (1975). Only a single scan of the Flat Crystal Spectrometer (FCS) on Solar Maximum Mission (SMM) in its 9-year lifetime was made of the Na X lines during a flare in 1980 (Phillips et al. 1982). Previous Na abundance analyses of the OVI-17 data gave log A(Na) = 6.26 (Walker et al. 1974) and of the Parkinson rocket data log A(Na) = 6.73 (Parkinson 1975) (on a scale log A(H) = 12). The Na X and Na XI X-ray lines have incidentally been observed in radiation from a laboratory (Z-pinch) device by Burkhalter et al. (1990).

Only rather approximate atomic data were available at the time of the Walker et al. (1974) and Parkinson (1975) analyses. However, significant advances have since been made to evaluate collisional excitation rate coefficients and ionization fractions needed for the evaluation of the abundance of sodium from X-ray line fluxes. The CHIANTI database and software package in the Interactive Data Language (IDL) SolarSoftWare system,
since its inception in the late 1990s (Dere et al. 1997, 2009), has also simplified analyses of X-ray and ultraviolet spectral data considerably. Excitation data for the Na X lines presently included in CHIANTI are interpolated values from other elements, but more recently Aggarwal et al. (2009) have calculated collisional excitation data specifically for He-like sodium with the close-coupling R-matrix code. Also, more refined ionization fractions assuming coronal ionization equilibrium have recently been calculated by Bryans et al. (2009).

The availability of new atomic data has inspired a fresh analysis, reported here, of the Na X X-ray lines seen in the SMM FCS spectral scan and the spectra obtained by Parkinson (1975). X-ray lines of Na X were identified by Phillips et al. (1982), with more detailed analysis of nearby lines by Landi & Phillips (2005). A slight revision of spectral line identifications is given here and a determination of the Na/Ne abundance ratio for this flare plasma, based on a remarkable coincidence of the contribution functions of the Na X w line and that of the Ne IX 1^5S_2–1^4P (υ4 or He-γ) line blended with the Na X w line. The Na/Ne abundance ratio is examined in the light of other recent abundance determinations and the nature of the FIP effect in solar coronal plasmas.

2. Observations

The SMM FCS observations (Phillips et al. 1982) were made during the decay stage of a GOES M1.5 class flare on 1980 August 25 with channel 2 of seven channels making up the instrument. Scanning flat crystals were mounted on a rotatable shaft, and radiation incident on them was via a grid collimator giving a 14 arcsec (FWHM) field-of-view. The high-precision Baldwin drive-encoder units used to rotate the drive led to very accurate wavelengths for observed spectral lines. The whole FCS could also be scanned spatially across an emitting region on the Sun. For the 1980 flare, a spatial scan was made over the flare emission near its onset to determine the location of the brightest point. The instrument was then pointed to this point, and a complete spectral scan taken. High-quality beryl (Be3Al2Si6O18, 2d = 15.96 Å) was the diffracting crystal of channel 2, giving a spectral resolution of 0.0056 Å at the wavelengths of the Na X lines near 11 Å. The scan took 17 min to accomplish, during which time there was a significant change in solar coronal emission. An analysis of the FCS data in this flare with CHIANTI (Landi & Phillips 2005) took this into account, dividing the scan into seven time bins. The Na X lines near 11 Å lay at the end of time bin 1 and the start of time bin 2 of the scan, when the flare emission and temperature were still high. An emission measure analysis by Landi & Phillips (2005) using only Fe lines (stages Fe XVII to Fe XXII) indicated a temperature of about 8 MK, which is reasonable for a M1.5 class flare a few minutes after its maximum emission. This analysis omitted emission lines of He-like ions such as Ne X and Mg XI since they indicated a much lower temperature, of about 1–4 MK. The reason for this is that the emission measure appears to have a bimodal distribution, with a flare component (~8 MK) and a lower-temperature component attributable to the non-flaring host active region which gives rise to the emission from the He-like ions. The Na X emission lines appear to be in the latter category. Support for such emission measure distributions is provided by analysis of Ar XVII X-ray lines observed during flares by the RESIK instrument (Sylwester et al. 2008); in that case, Ar XVII line ratios were best fitted by a bimodal emission measure distribution having temperatures of 4.5 MK and 16 MK.

Also, analysis of broad-band data from the RHESSI instrument in its A0 attenuator state (Phillips et al. 2006) similarly indicates that there is a non-flaring component of emission, with temperature corresponding to the active region, as well as a hotter flare component.

The FCS channel 2 spectral scan over the 10.9–11.3 Å range is shown in each of the four panels of Fig. 1 (histogram plot). In these plots, FCS count rates have been converted to absolute spectral irradiance units using pre-launch intensity calibration factors. The background emission is largely due to fluorescence of the crystal material with the solar continuum making a minor contribution. The theoretical wavelengths of Na X lines are indicated.

The rocket-borne crystal spectrometers described by Parkinson (1975) were launched on a stabilised Skylark rocket on 1971 November 30. The instruments viewed a non-flaring active region on the Sun through a grid collimator with field of view equal to 3 arcmin (FWHM). Two of the spectrometers scanned through the region of the Na X lines near 11 Å with KAP (2d = 26.64 Å) and gypsum (2d = 15.19 Å) crystals. As the data are no longer in digital form, the spectra in the region of the Na X lines (10.9–11.4 Å) from Fig. 3 of Parkinson (1975) were hand-digitised for the purposes of this analysis. The photon count rate is higher in the KAP crystal scan and so the spectrum has high statistical quality. This scan is shown in Fig. 2. The temperature is likely to be lower than the FCS scan in Fig. 1 and the line feature at 11.152 Å, if real, could be the Na IX satellites q and r; the theoretical position of line q is indicated.
Fig. 2. X-ray spectrum (histograms) in the 10.9–11.3 Å range obtained with a rocket-borne KAP crystal spectrometer of a non-flaring active region in 1971 (Parkinson 1975). The spectrum is compared with synthetic spectra having temperatures 1 MK, 1.5 MK, 2 MK, and 2.5 MK (indicated in each panel) and an assumed Ne/Na abundance ratio equal to a coronal value of 0.07. Na IX satellites are included in the synthetic spectra. Line styles are as for Fig. 1. (A colour version is available on the on-line journal. On-line journal version key: black histogram = observed spectrum; coloured curves are theoretical spectra, with code blue = Na X lines alone; green = Na X and Ne IX lines; red = with Fe XVII lines.)

3. Atomic data and line identifications

3.1. The spectrum in the 10.9–11.3 Å region

Na X lines in the X-ray region include a group of four lines with transitions of the type 1s^2−1s2l (l = s, p) and higher members of the 1s^2−1snl series. Using the notation of Gabriel (1972), the n = 2 lines are, in increasing order of wavelength, identified with letters w (transition 1s^2 1S0−1s2p^3P_1, wavelength 11.003 Å), x (1s^2 1S0−1s2p^3P_2, 11.080 Å), y (1s^2 1S0−1s^2p^1P_0, 11.083 Å), and z (1s^2 1S0−1s2s^3S_1, 11.192 Å). The wavelengths, quoted from CHIANTI, are from Ralchenko et al. (2008). Dielectronic satellites with transitions 1s^n2l'−1s2p^1l' occur in great profusion in the neighbourhood of the w−z lines, but with only a few that are significant at lower temperatures, particularly satellites j and k (transitions 1s^22p−1s2p^3) which blend with line z and satellites q and r (1s^22s−1s2s2p). Numerous satellites with very high n values occur near line w and converge on it; individually they are not important but their cumulative contribution is up to about 10% of line w.

The Ne IX 1s^2 1S0−1s4p^1P_1 (w4) line occurs very near the Na X w line, but how near was unclear from early atomic structure calculations. Those of Vainshtein & Safonova (1978) gave the wavelength as 11.025 Å, longward of the Na X w line by an amount easily resolvable with the FCS and Parkinson instruments. Using the wavelengths of Wiese et al. (1969), Parkinson (1975) was led to identify a line feature at 11.027 Å as the Ne IX w4 line. However, the more recent MCDF calculations of Chen et al. (2006) seem to have established that this line is at 11.000 Å, just 0.003 Å away from the Na X w line. In light of this, the feature at 11.027 Å is now identifiable with an Fe XVII line with transition 2s^2 2p^6 1S0−2s 2p^6 4P_1 (wavelength 11.023 Å according to Landi & Phillips 2005). More intense Fe XVII lines occur at 11.133 Å and 11.253 Å. Table 1 lists identifications and wavelengths of the principal lines in this region.

Ne VIII satellite lines with transitions 1s^2 nl−1s nl4p are expected to form weak features to the long-wavelength side of the Ne IX w4 line, but are outside the range of interest here: the most prominent are those in the 1s^22p−1s2p4p array which are located at ~11.45 Å.

3.2. Contribution functions

The contribution function G(T_e), defining the temperature range of significant emission of a line emitted by an ion (stage +m) of element X in a transition from an excited level j to the ground level, is defined by (e.g. Phillips et al. 2008)

$$G(T_e) = \frac{N(X)^{+m} N(X)^{+-m} N(H)^{+m} N(H)^{+-m}}{N_e^{+m} N(H)^{+m} N_e^{+m} N_e^{+-m}}$$

where the number densities N are of the excited level of ion X^{+m}, the ion X^{+-m} (all levels summed), the element X (all ionization stages m), and hydrogen (H); and N_e is the electron density. The abundance of X relative to H is N(X)/N(H) = A(X), and for a coronal plasma N(H)/N_e = 0.8. These functions can be determined from CHIANTI with the user supplying the line wavelength and a chosen set of ionization fractions and element abundances. Figure 3 shows the CHIANTI G(T_e) functions for the lines of interest here, viz. Na X w, Ne IX w4, and the Fe XVII line at 11.129 Å. The excitation data for the Na X lines used in these calculations are from interpolation of distorted-wave calculations for neighbouring ions, while those for the Ne IX lines are from the R-matrix calculations of Chen et al. (2006). The recent ionization fractions of Bryans et al. (2009) were used, as were the coronal abundances of Feldman et al. (1992a), in which low-FIP elements have abundances enhanced over photospheric values by a factor of ~4 but high-FIP element abundances are equal to photospheric values (see Sect. 3.5).

While the Fe XVII G(T_e) curve steeply rises at T_e ≤ 4 MK and falls at T_e ≥ 10 MK, reflecting the fractional abundance of the Fe^{16} ion, both the Na X and Ne IX lines have contribution functions that are much more slowly decreasing with T_e. There is a remarkable coincidence of the Na X and Ne IX curves for T_e ≤ 4 MK, and even at higher temperatures the Na X curve is consistently only a factor 3 above the Ne IX curve. This provides a means for determining the Na/Ne abundance if the two lines, which are practically unresolvable with the FCS and Parkinson spectrometers, are mostly emitted at temperatures 4 ≤ T_e ≤ 50 MK.

3.3. Theoretical Na X line fluxes

The principal Na X X-ray lines in the 10.9–11.3 Å range are mostly excited by electron collisions, and so collisional excitation rate coefficients are of considerable importance in
(Na\textsuperscript{19}) to produce a doubly excited state which then radiatively de-excites. The flux at the Earth (distance from Sun = 1 AU) of the satellite $F_{\text{sat}}$ formed in this way is given by

$$F_{\text{sat}} = 2.07 \times 10^{-16} \frac{N(\text{Na}\textsuperscript{19}) N_e V}{A_A \sum A_i} \exp\left(\frac{-E_{\text{exc}}/k_B T_e}{T_e^{3/2}}\right)$$

where $A_i$ and $A_A$ are the radiative and autoionization probabilities from the satellite’s upper level respectively, $E_{\text{sat}}$ the energy of the upper level with respect to the ground level of the Na\textsuperscript{19} ion, $V$ the flare emitting volume, and $k_B$ is Boltzmann’s constant. The term $N(\text{Na}\textsuperscript{19}) N_e V$ can be rewritten $0.8 f (\text{Na}\textsuperscript{19}) A(\text{Na}/EM$ where the volume emission measure is $EM = N_e^2 V$ and the fraction of Na\textsuperscript{19} ions, $N(\text{Na}\textsuperscript{19})/N(\text{Na})$, is $f(T_e)$. The intensity factor $B_{\text{sat}}$, defined by

$$B_{\text{sat}} = \frac{A_A A_i}{A_A + \sum A_i},$$

is calculated by the Cowan HFR code together with all the radiative and autoionization probabilities and the satellite wavelengths.

Input to the code is the satellite array and value of $E_{\text{sat}}$. Single-electron radial functions are calculated by the code and combined with Slater-Condon theory to give energy levels. Previous experience (Phillips et al. 1984) has shown that choosing 100% for the scaling of the Slater parameters in the code gives good results for X-ray transitions, though there is generally a small wavelength shift $\Delta \lambda$ between the wavelength of the He-like ion line $w$ and that of satellites with very high values of $n$ for the spectator electron, which should converge on line $w$. In running the code for Na\textsuperscript{IX} satellites, we took 100% scaling of the Slater parameters and added $\Delta \lambda = +0.001 \, \text{Å}$ to the Cowen satellite wavelengths since this value of $\Delta \lambda$ is needed to achieve agreement between the wavelengths of high-$n$ satellites and the Na\textsuperscript{X} $w$ line.

Table 2 lists data for a selection of satellites – wavelengths, $B_{\text{sat}}$, and $E_{\text{sat}}$ – from the calculations, which included satellites with spectator electrons having $n = 2s$, $2p$, $3s$, $3p$, $3d$, etc., extending up to $n = 6p$. We generated data for $n = 10p$ to determine the wavelength shift $\Delta \lambda$. As was found by Gabriel (1972) and others, satellites $j$ and $k$ (see Table 2) are the most intense, i.e. have the largest values of $B_{\text{sat}}$. They are both within 0.004 Å of the Na\textsuperscript{X} $z$ line at 11.192 Å. This is in agreement with other calculations of satellite line wavelengths for elements having similar atomic number, notably Mg (e.g. Steenman-Clark et al. 1984). For Ca ($Z = 20$), satellite $k$ becomes resolved from line $z$, while for Fe ($Z = 26$), both $j$ and $k$ are resolved.

Inner-shell excitation can also give rise to satellites in the 1s\textsuperscript{2}2s–1s2s2p array for solar flare densities (at much higher densities, inner-shell excitation gives rise to satellites in other arrays also). Again, the current version of CHIANTI does not have atomic data relating to these satellites. As at least satellites $q$ and $r$ (see Table 2) in the 1s\textsuperscript{2}2s–1s2s2p array are expected to be important, Maxwellian-averaged collision strengths $\Upsilon(T_e)$ for the entire array were calculated using the Flexible Atomic Code of Gu (2003). Assuming that the de-excitation is entirely the radiative transition to the ground level 1s\textsuperscript{2}2s\textsuperscript{2}S\textsuperscript{1/2}, the satellite line fluxes are then given by

$$F_{\text{sat}} = \frac{N(\text{Na}\textsuperscript{19}) N_e V}{4\pi (\text{AU})^2} \times \frac{8.63 \times 10^{-6} \Upsilon(T_e)}{T_e^{1/2}} \exp\left(-E_{\text{exc}}/k_B T_e\right)$$

where $E_{\text{exc}}$ is the excitation energy of the satellite line. Figure 4 shows the calculated $\Upsilon$ functions for excitation from the 1s\textsuperscript{2}2s\textsuperscript{2}S\textsuperscript{1/2} level to the levels indicated.
and Fe XXIII lines seen in the FCS spectrum and which were fitted by an 8 MK component in the analysis by Landi & Phillips (2005). The Fe XVII lines are emitted by plasma with $T_e > 3$ MK (see Fig. 3) so contributions from both the active region and flare may be expected. The synthesis program computed spectra in a temperature grid from 0.8 MK to 5 MK.

The Na X lines were included in the synthesis program from the Aggarwal et al. (2009) atomic data (Sect. 3.3) and the Na IX satellites, both those excited by dielectronic recombination and those formed by inner-shell excitation, from the data discussed in Sect. 3.4. The Ne IX a4 line was included using fluxes from CHANTI, as well as the much weaker intercombination line 1s$^2$ 3S$_0$−1s4p 3P$_1$, unresolved from the a4 line. Other lines were also included, most notably Fe XVII lines; lines of Fe XIX and Fe XXIII had negligible fluxes in the temperature range considered. The CHANTI Fe XVII line wavelengths differ somewhat from the observed FCS wavelengths; as the FCS wavelengths are expected to be very precise (uncertainties $\leq 2$ mA in this region), the FCS wavelengths from an original analysis (Phillips et al. 1982) were used. Fluxes of the Na X $w$, $x$, $y$, and $z$ lines were obtained from the collisional excitation data of Aggarwal et al. (2009) which were inserted into files that could be read by the CHANTI software. The Na IX satellite fluxes were calculated from Eqs. (2) and (4). Gaussian profiles were applied to spectral lines that were a convolution of the thermal Doppler broadening ($FWHM$ width $\Delta \lambda_D$) and the instrumental profile, defined by the crystal rocking curve ($FWHM$ width equal to $\Delta \lambda_{oc}$), assumed to be Gaussian. The widths are given respectively by

$$\Delta \lambda_D = 1.665 \frac{\lambda}{c} \left( \frac{2kT_{\text{ion}}}{M_{\text{ion}}} \right)^{1/2}$$

where $T_{\text{ion}}$ is the temperature of the emitting ion, taken to be $T_e$, and $M_{\text{ion}}$ the ion mass, and

$$\Delta \lambda_{oc} = 2d \cos \theta \Delta \theta$$

where the crystal rocking curve is $\Delta \theta$. A pre-launch measured value of $\Delta \theta$ for the FCS observing the Na X lines of 100 arcsec was taken for the FCS spectrum. The differing ion masses for the

Notes. (a) Wavelengths from Cowan code + 0.001 Å; (b) Notation of Gabriel (1972); Bely-Dubau et al. (1979); (c) Numbers in parentheses are powers of ten; (d) Lines also formed by inner-shell excitation.

Fig. 4. Maxwellian-averaged collision strengths $\gamma(T_e)$ as a function of temperature for excitation from the Li-like Na (Na X) ion ground level 1s$^2$2s$^2$S$_{1/2}$ to the upper levels of satellites $q, r, s, t, u, v$ (transitions given in Table 2) calculated using the Flexible Atomic Code (FAC). (A colour version is available in the on-line journal, with different colours for the $\gamma$ curves for excitation to each upper level.)

3.5. Synthetic spectra

A spectral synthesis program was written with the specific intention of matching the Na X and Ne IX lines, together with Na IX satellites, in the 10.9–11.3 Å region as observed by the FCS and Parkinson spectrometer. It is assumed, as was found from the RESIK flare observations of Ar XVII line ratios (Sylwester et al. 2008) and analysis of broad-band spectra from RHESSI in its A0 attenuator state (Phillips et al. 2006), that a two-component emission measure distribution describes the observed spectra, a low-temperature component (1–4 MK) appropriate for the Na X and Ne IX emission from the non-flaring active region and a higher-temperature component for the flare emission proper (FCS spectrum) or for a hotter part of the active region if present (Parkinson spectra); it is this component that is responsible for most of the Fe ion line emission in this region, including Fe XII and Fe XXIII.
Na, Ne Ix, and Fe XVII lines were taken into account, though the FCS instrumental broadening dominates the convolved line profile. For the Parkinson rocket spectra, the instrument profile was empirically taken to be 3 times the FCS rocking curve width to match the observed line profiles. As in the calculation of contribution functions (Sect. 3.2), the Na and Ne ionization fractions were taken from Bryans et al. (2009).

Element abundances were taken for an average coronal plasma using values from Feldman et al. (1992a) (included as “coronal abundances” in CHIANTI). An initial value of 0.071 is thus taken for the sodium-to-neon abundance ratio – \( A(\text{Na})/A(\text{Ne}) \) – but in our analysis it is a free parameter to be determined from line flux measurements. The Fe abundance likewise is taken to be \( \log A(\text{Fe}) = 8.10 \) (on a scale \( \log A(\text{H}) = 12 \)). This is supported by measurements of broad-band RHESSI flare spectra Phillips et al. (2006), indicating that of 25 flares, 19 had estimated abundances \( \log A(\text{Fe}) \) that were within 20% of the Feldman et al. (1992a) value. Although spatial variations in coronal abundances have been noted (Feldman et al. 1992b), the chief variations are those during impulsive flares and above strong sunspot magnetic fields, when low-FIP elements appear to have photospheric abundances.

4. Results

Figure 1 shows the SMM FCS spectrum for the flare of 1980 August 25. In this figure, the observed spectrum is compared with four synthetic spectra with \( T_e = 2, 3, 4, 5 \) MK, all with the coronal value of \( A(\text{Na})/A(\text{Ne}) = 0.071 \). In each case, the synthetic spectra were adjusted so that the blend of the Na Ix \( z \) line with the Na IX \( j \) and \( k \) satellites (feature at 11.192 Å) is fitted, leaving the blend of the Na IX \( w \) line and the Ne IX \( w4 \) line (feature at 11.003 Å) free as well as the barely significant Na Ix \( y \) line at 11.083 Å. At the temperatures shown, the Na IX satellites \( j \) and \( k \) are very weak, the ratio of the sum of these two satellites to the Na Ix \( z \) line varying from 0.24 to 0.045 over the range \( T_e = 2 \) MK to 5 MK. The satellites \( q \) and \( r \) are also weak, the feature at 11.15 Å formed by them being unobserved by the FCS. In addition the ratio of blended Na IX \( w \) to the Ne IX \( w4 \) lines is only weakly \( T_e \)-dependent (Fig. 3). In fact, the only indication of temperature in the theoretical spectra in Fig. 1 is the presence of nearby Fe XVII lines at 11.023 Å, 11.129 Å, and 11.250 Å. The best-fit temperature to the FCS spectrum is clearly \( T_e = 3 \) MK. However, the emission measure analysis of Landi & Phillips (2005) shows that much of the emission of these and other more highly ionized Fe lines for this particular stage of the August 25 flare occurs at a higher temperature, around \( T_e \approx 8 \) MK, with He-like ion line emission such as Na X and Ne IX occurring at lower temperatures indicative of the host active region. The agreement of the FCS and theoretical spectra at \( T_e = 3 \) MK for the Fe XVII lines in Fig. 1 may therefore be regarded as coincidental.

As values of temperature over the range 2–5 MK only slightly affect the Na X and Ne Ix line emission, the effect of the abundance ratio \( A(\text{Na})/A(\text{Ne}) \) may be examined; this is shown in Fig. 5. The FCS spectrum is compared with theoretical spectra, calculated at \( T_e = 3 \) MK, for three values of \( A(\text{Na})/A(\text{Ne}) \): 0.14, 0.07, 0.035, i.e. the coronal value of Feldman et al. (1992a) multiplied by 2, 1, and 0.5 respectively. Clearly the best match is for \( A(\text{Na})/A(\text{Ne}) = 0.07 \). Ruling out the values of 0.14 and 0.035 for this ratio (top and bottom panels of Fig. 5) leads to an estimated precision that is approximately 50%. This estimate of the abundance ratio is significantly larger than the photospheric abundance ratio, \( A(\text{Na})/A(\text{Ne}) = 0.02 \) (Asplund et al. 2009), and suggests an enhancement of about 3 to 4 in the abundance of Na in the corona if the active region plasma is coronal in origin.

For the Parkinson rocket spectra, the emission arises from a lower-temperature plasma indicative of a non-flaring active region. Figure 2 shows the KAP crystal scans compared with four theoretical spectra with \( T_e = 1, 1.5, 2, \) and 2.5 MK and \( A(\text{Na})/A(\text{Ne}) = 0.07 \). At \( T_e \leq 2 \) MK, the ratio of the Na X–Ne IX \( w4 \) blend at 11.002 Å to the Na X \( z \) line at 11.191 Å is sensitive to \( T_e \), largely through the contribution of the Na IX satellites \( j \) and \( k \) to Na X \( z \) line. The ratio of the sum of these satellites to Na X \( z \) over the temperature range 1 MK to 2.5 MK varies from 2.5 to 0.14. Of the four theoretical spectra shown, the one with \( T_e = 1 \) MK best fits the KAP spectrum. Although only just significant (total photon counts per 0.025 s equal to about 16), the feature at 11.15 Å can be identified with the blend of Na IX satellites \( q \) and \( r \); the appearance of these satellites confirms the temperature of \( \sim 1 \) MK. This conclusion is also supported by the g gypsum crystal scan though this has lower statistical quality. In the original analysis of Parkinson (1975), an emission measure distribution peaking at 3 MK was found, rather more than is found here with improved atomic data. The comparatively low temperature for this active region that we find is in keeping with the fact that solar activity was at a rather low level when the observations were taken.

If the temperature of the active region is only \( \sim 1 \) MK, the Fe XVII lines at 11.023 Å, 11.129 Å, and 11.250 Å should not be so strong. The ionization fractions of Bryans et al. (2009) indicate that there is a negligible fraction of Fe\textsuperscript{16} ions for \( T_e \leq 1.5 \) MK (Fig. 3). As with the FCS spectra, a higher-temperature component might be present. However, in that case the Na X and Ne X line emission would be much higher, the fitted temperature would be correspondingly higher, and disagreements in the fit to the Na X–Ne IX \( w4 \) blend and the weak 11.15 Å line feature, formed by satellites \( q \) and \( r \), would result. There is a possibility, then, that the Fe\textsuperscript{16} ion fractions at \( T_e \leq 1.5 \) MK are in error, and that there is in fact a non-negligible fraction of Fe\textsuperscript{16} ions at very low temperatures.

![Fig. 5. The FCS spectrum in the 10.9–11.3 Å range during the flare of 1980 August 25 compared with theoretical spectra for \( T_e = 3 \) MK and three values of the abundance ratio \( A(\text{Na})/A(\text{Ne}) \) (indicated in each plot). Line styles for the theoretical curves as for Fig. 1. Two of the Fe XVII lines are off-scale to show better the agreement of the theoretical curves with the observed Na X and Ne Ix line emission. (A colour version is available in the on-line journal. On-line journal version key is the same as for Fig. 1.)](image-url)
5. Conclusions

In this work, recent collisional excitation results for Na\textsubscript{X} X-ray line emission have been applied to solar spectra for the first time, together with new atomic data for Na\textsubscript{IX} satellites, formed by both dielectronic recombination and inner-shell excitation. From these and other data from the CHIANTI atomic code, synthetic spectra were calculated as a function of electron temperature $T_e$.

To date, the only observed spectra taken with high-resolution spectrometers in the 10.9–11.3 Å range are from the SMM Flat Crystal Spectrometer (a single scan during the decay of a M1.5 flare) and two rocket-borne scanning crystal spectrometers in 1971 viewing a non-flaring active region. Comparison of the FCS and calculated spectra in the 10.9–11.3 Å range shows that the Na\textsubscript{X} X-ray lines with nearby Na\textsubscript{IX} dielectronic satellites yield a Na/Ne abundance ratio through the blend of the Na\textsubscript{X} $w$ (resonance) line with the Ne\textsubscript{IX} $u4$ ($1s^2 1S_0-1s4p 1P_1$) line, these lines having almost identical contribution functions $G(T_e)$ for the low temperatures considered here. The value obtained, $A$(Na)/$A$(Ne) = 0.07 ± 50%, is the coronal value of Feldman et al. (1992a) to within uncertainties. It is significantly higher than the photospheric value, 0.020, and suggests that sodium ionization or recombination rates may be needed.
