Irreversibility is one of the most intriguing concepts in physics. While microscopic physical laws are perfectly reversible, macroscopic average behavior has a preferred direction of time. According to the second law of thermodynamics, this arrow of time is associated with a positive mean entropy production. Using a nuclear magnetic resonance setup, we measure the nonequilibrium entropy produced in an isolated spin-1/2 system following fast quenches of an external magnetic field and experimentally demonstrate that it is equal to the entropic distance, expressed by the Kullback-Leibler divergence, between a microscopic process and its time-reverse. Our result addresses the concept of irreversibility from a microscopic quantum standpoint.

The microscopic laws of classical and quantum mechanics are time symmetric, and hence reversible. However, paradoxically, macroscopic phenomena are not time-reversal invariant [1,2]. This fundamental asymmetry defines a preferred direction of time that is characterized by a mean entropy production. Regardless of the details and nature of the evolution at hand, such entropy production is bound to be positive by the second law of thermodynamics [3]. Since its introduction by Eddington in 1927 [4], the thermodynamic arrow of time has not been tested experimentally at the level of a quantum system.

Introduced by Clausius in the form of an uncompensated heat, the importance of the entropy production in nonequilibrium statistical physics has been recognized by Onsager and further developed by Meixner, de Groot and Prigogine [5]. Defined as $\Sigma = \beta(W - \Delta F)$, for a system at constant inverse temperature $\beta = 1/(k_B T)$, where $W$ is the total work done on the system and $\Delta F$ the free energy difference ($k_B$ is the Boltzmann constant), it plays an essential role in the evaluation of the efficiency of thermal machines, from molecular motors to car engines [3].

Starting with Boltzmann’s work on the so-called $H$-theorem, the quest for a general microscopic expression for the entropy production, especially far from equilibrium, has been a challenge for more than a century [11]. In the last years, formulas for the entropy production and entropy production rate in terms of the microscopic density operator $\rho$ of a system have been obtained for relaxation [6], transport [2], and driven processes in closed and open quantum systems [8,9]. At the same time, the recent development of fluctuation theorems [10,11] has led to a sharpening of the formulation of the second law. Regardless of the size of a system, the arrow of time originates from the combination of an explicit time-dependence of the Hamiltonian of the system and the specific choice of an initial equilibrium state. While the first ingredient breaks time homogeneity (thus inducing the emergence of an arrow of time), the second specifies its direction [12].

In small systems, thermal and quantum fluctuations are both significant, and fluctuation theorems quantify the occurrence of negative entropy production events during individual processes [13]. In particular, the average entropy production $\langle \Sigma \rangle$ for evolution in a time window $\tau$ has been related to the Kullback-Leibler relative entropy between states $\rho^F_t$ and $\rho^{B}_{\tau-t}$ along the forward and backward (i.e. time reversed) dynamics [14,16] (see Fig. 1). Explicitly

$$\langle \Sigma \rangle = S(\rho^F_t || \rho^{B}_{\tau-t}) = \text{tr} [\rho^F_t (\ln \rho^F_t - \ln \rho^{B}_{\tau-t})] . \quad (1)$$

The above equation quantifies irreversibility at the microscopic quantum level and for the most general dynamical process responsible for the evolution of a driven closed system. A process is thus reversible, $\langle \Sigma \rangle = 0$, if forward and backward microscopic dynamics are indistinguishable. Nonequilibrium entropy production and its fluctuations have been measured in various classical systems, ranging from biomolecules [17].

![Figure 1](image_url)

Figure 1. (Color online) A quantum system (with Hamiltonian $\mathcal{H}_0^n$) is initially prepared in a thermal state $\rho^0_{eq}$ at inverse temperature $\beta$. It is driven by a fast quench into the nonequilibrium state $\rho^F_t$ along a forward protocol described by the Hamiltonian $\mathcal{H}_t^F$. In the backward process, the system starts in the equilibrium state $\rho^{B}_{eq}$ corresponding to the final Hamiltonian $\mathcal{H}_t^B$ and is driven by the time-reversed Hamiltonian $\mathcal{H}^{B}_{\tau-t} = -\mathcal{H}^{F}_{t} \leftrightarrow \mathcal{H}^{B}_{\tau-t}$. The entropy production $\langle \Sigma \rangle$ at time $t$ is given by the Kullback-Leibler divergence between forward and backward states $\rho^F_t$ and $\rho^{B}_{\tau-t}$ (cf. Eq. 1).
and colloidal particles [18] to levitated nanoparticles [19] (see Refs. [20, 21] for a review). Evidence of time asymmetry has been further observed in a driven classical Brownian particle and its electrical counterpart [22]. However, quantum experiments have remained elusive so far, owing to the difficulty to measure thermodynamic quantities in the quantum regime. To date, Eq. (1) has thus never been tested.

In this Letter, we use a nuclear magnetic resonance (NMR) setup to provide a clear-cut assessment of Eq. (1) where \( \langle \Sigma \rangle \) and \( S \left( \rho_{\Sigma}^{F} \parallel \rho_{\Sigma}^{B} \right) \) are tested and evaluated independently. Our methodological approach is founded on the reconstruction of the statistics of work and entropy, following a non equilibrium process implemented on a two-level system, therefore assessing the emergence of irreversibility (and the associated arrow of time) starting from a genuine microscopic scale.

We consider a liquid-state sample of chloroform, and encode our system in the qubit embodied by the nuclear spin of \(^{13}\text{C} \) [23–25]. The sample is placed in the presence of a longitudinal static magnetic field (whose direction is taken to be along the positive \( z \) axis) with strong intensity, \( B_0 \approx 11.75 \text{ T} \). The \(^{13}\text{C} \) nuclear spin precesses around \( B_0 \) with Larmor frequency \( \nuC/2\pi \approx 125 \text{ MHz} \). We control the system magnetization through rf-field pulses in the transverse \( (x \text{ and } y) \) direction [25]. The initial thermal state \( \rho_0^{\text{eq}} \) of the \(^{13}\text{C} \) nuclear spin (at inverse temperature \( \beta \)) is prepared by suitable sequences of transversal radio-frequency (rf)-field and longitudinal field-gradient pulses. We use the value \( k_B T/h = 1.56 \pm 0.07 \text{ kHz} \) (corresponding to an effective temperature of \( T \approx 75 \pm 3 \text{nK} \)) throughout the experiment for the initial \(^{13}\text{C} \) nuclear spin thermal states. A sketch of the experimental setup is provided in Fig. 2.

The system is driven out of equilibrium to the state \( \rho_t^{\text{eq}} \) by a fast quench of its Hamiltonian (denoted as \( \mathcal{H}_t^{\text{eq}} \) in this forward process) lasting a time \( \tau \). We experimentally realize this quench by a transverse time-modulated rf field set at the frequency of the nuclear spin. In a rotating frame at the spin Larmor frequency, the Hamiltonian regulating the forward process is

\[
\mathcal{H}_t^{\text{eq}} = 2\pi \nu \left[ \sigma_z^{\text{eq}} \cos \phi(t) + \sigma_y^{\text{eq}} \sin \phi(t) \right]
\]

Figure 3. (Color online) (a) [(b)] Evolution of the Bloch vector of the forward [backward] spin-1/2 state \( \rho_t^{\text{eq}} \parallel \rho_{\Sigma}^{B, -1} \) during a quench of the transverse magnetic field, obtained via quantum state tomography. A sampling of 21 intermediate steps has been used. The initial magnetization (gray arrow) is parallel to the external rf-field, aligned along positive \( x \) [\( y \)] axis for the forward [backward] process. The final state is represented as a red [blue] arrow. (c) Polar projection (indicating only the magnetization direction) of the Bloch sphere with the trajectories of the spin. Green lines represent the path followed in a quasistatic \( \tau \to \infty \) process.

The system is driven out of equilibrium to the state \( \rho_t^{\text{eq}} \) by a fast quench of its Hamiltonian (denoted as \( \mathcal{H}_t^{\text{eq}} \) in this forward process) lasting a time \( \tau \). We experimentally realize this quench by a transverse time-modulated rf field set at the frequency of the nuclear spin. In a rotating frame at the spin Larmor frequency, the Hamiltonian regulating the forward process is

\[
\mathcal{H}_t^{\text{eq}} = 2\pi \nu (t) \left[ \sigma_z^{\text{eq}} \cos \phi(t) + \sigma_y^{\text{eq}} \sin \phi(t) \right]
\]

with \(\sigma_{x,y,z} \) the Pauli spin operators, \( \phi(t) = \pi t/(2\tau) \), and \( \nu(t) = \nu_0 (1 - t/\tau) + \nu_\tau t/\tau \) the (linear) modulation of the rf-field frequency over time \( \tau \), from value \( \nu_0 = 1 \text{ kHz} \) to \( \nu_\tau = 1.8 \text{ kHz} \). With these definitions, the initial thermal state of the \(^{13}\text{C} \) system is \( \rho_0^{\text{eq}} = \exp(-\beta \mathcal{H}_0^{\text{eq}})/Z_0 \), where \( Z_0 \) is the partition function at time \( t = 0 \).
In order to reconstruct the work and entropy production statistics of the $^{13}$C quenched dynamics, we use the method proposed in Refs. [26–28] and illustrated in detail in Ref. [29]. We consider an ancillary qubit embodied by the $^1$H nuclear spin of our sample (Larmor frequency $\omega_1/2\pi \approx 500$ MHz) and exploit the natural scalar coupling between the $^1$H and $^{13}$C nuclear spins to implement the interferometer needed to reconstruct the statistics of the work done by $^{13}$C following the quench [29]. The method assumes a unitary dynamics of both system and ancilla, a condition that is met with excellent accuracy in our experiment. In fact, the spin-lattice relaxation times, measured by inversion recovery pulse sequence, are $(T_1^H, T_2^C) \approx (7.36, 10.55)$ s. The transverse relaxations, obtained by CPMG pulse sequence, have characteristic times $(T_2^H, T_2^C) \approx (4.76, 0.33)$ s. We thus study processes of maximal duration $\tau \sim 10^{-4}$ s and consider total data acquisition times for the reconstruction of the work and entropy statistics within 0.1 ms and 126 ms, being smaller than $T_1^{HC}$. This enables us to disregard any energy exchange with the system environment during the quenched dynamics. The effects of the $^{13}$C transverse relaxation ($T_2^C$) can be partially overcome by a refocussing strategy in the reconstruction procedure.

We implement the backward process, shown in Fig. 1, by driving the system with the time-reversed Hamiltonian, $H^B_\tau = H^C_{t-\tau}$, from the equilibrium state, $\rho^{eq}_\tau = \exp(-\beta H^B_\tau)/Z_\tau$, which corresponds to the final Hamiltonian $H^C_\tau$ ($Z_\tau$ here denotes the partition function at time $t$). The intermediate $^{13}$C states during the field quench are $\rho_\tau^F = U_\tau \rho^{eq}_\tau U_\tau^\dagger$ and $\rho_{t-\tau}^B = V_{t-\tau} \rho^{eq}_\tau V_{t-\tau}^\dagger$, where the evolution operators satisfy the time-dependent Schrödinger equations $\dot{U}_\tau = -i H^C_\tau U_\tau$ and $\dot{V}_\tau = i H^C_{t-\tau} V_\tau$ with the initial conditions $U_0 = I$ and $V_0 = I$.

Work is performed on the system during the forward and backward processes. The corresponding probability distributions $P^F(W)$ are related via the Tasaki-Crooks fluctuation relation [30,32]

$$P^F(W) / P^B(-W) = e^{\beta(W - \Delta F)}.$$  

Equation (3) characterizes the positive and negative fluctuations of the quantum work $W$ along single realizations. It holds for any driving protocol, even beyond the linear response regime, and is a generalization of the second law to which it reduces on average, $\langle \Sigma \rangle = \beta (\langle W \rangle - \Delta F) \geq 0$.

We demonstrate the importance of the arrow of time by determining both sides of the equation independently. We first evaluate the Kullback-Leibler relative entropy between forward and backward processes and different quench times. As a second step, we measure the probability distribution $P(\Sigma)$ of the irreversible entropy production using the Tasaki-Crooks relation Eq. (3). Employing NMR spectroscopy [23] and the method described in Refs. [26–28] (cf. Ref. [29] for a detailed analysis), we determine the forward and backward work distributions, from which we extract $\beta$, $W$ and $\Delta F$, and hence the entropy produced during each process. The measured nonequilibrium entropy distribution is shown in Fig. 4(a). It is discrete as expected for a quantum system. We further observe that both positive and negative values occur owing to the stochastic nature of the problem. However, the mean entropy production is positive (red line) in agreement with Clausius inequality $\langle \Sigma \rangle \geq 0$ for an isolated system. We have thus directly tested one of the fundamental expressions of the second law of thermodynamics at the level of an isolated quantum system [3].

A comparison of the mean entropy production with the Kullback-Leibler relative entropy between forward and backward states is displayed in Fig. 4(b) as a function of the
quench time. We observe good agreement between the two quantities within experimental errors that are due to inhomogeneities in the driving rf-field and non-idealities of the field modulation. These results provide a first experimental confirmation of Eq. (1) and the direct verification of the thermodynamic arrow of time in a driven quantum system. They quantify in a precise manner the intuitive notion that the faster a system is driven away from thermal equilibrium (i.e. the bigger the mean entropy production or the shorter the driving time $\tau$), the larger the degree of irreversibility, as measured by the relative entropy between a process and its time reversal.

In the linear response regime, Onsager has derived generic expressions for the entropy production which form the backbone of standard non equilibrium thermodynamics. These results are, however, limited to systems that are driven close to thermal equilibrium. By contrast, Eq. (1) holds for any driving protocol and thus arbitrarily far from equilibrium.

In order to check the general validity of Eq. (1), we use the linear response (LR) approximation of the mean work $\langle W_{\text{LR}} \rangle$, $\langle W_{\text{LR}} \rangle = \Delta F + \beta \Delta W^2/2$, where $\Delta W^2$ is the variance of the work, to obtain the mean entropy production $\langle \Sigma_{\text{LR}} \rangle = \beta^2 \Delta W^2/2$. Fig. 4(c) shows the experimental values of $\langle \Sigma \rangle$ and $\langle \Sigma_{\text{LR}} \rangle$ as a function of the quench duration. We note that the measured irreversible entropy production $\langle \Sigma \rangle$ is close yet systematically distinct from its linear response approximation $\langle \Sigma_{\text{LR}} \rangle$, the difference being more pronounced for fast quenches (small $\tau$), as expected. Fig. 4(c) thus suggests that the quenches implemented in the experiment are performed somewhat away from the nonlinear response regime. We also mention that we achieve good agreement between experimental data (dots) and numerical simulations (dashed lines) (29).

Conclusions.—We have assessed the emergence of the arrow of time in a thermodynamically irreversible process by using the tools provided by the framework of non equilibrium quantum thermodynamics. We have implemented a fast quenched dynamics on an effective qubit in an NMR setting, assessing both the mean entropy produced across the process and the distance between the state of the system and its reverse version, at all times of the evolution. Let us discuss the physical origin of such time-asymmetry in a closed quantum system. Using an argument put forward by Loschmidt in the classical context, its time evolution should in principle be fully reversible (1). How can then a unitary equation, like the Schrödinger equation, lead to Eq. (1) that contains a strictly nonreversible term? The answer to this puzzling question lies in the observation that the description of physical processes requires both equations of motion and initial conditions (13). The choice of an initial thermal equilibrium state singles out a particular value of the entropy, breaks time-reversal invariance and thus leads to the arrow of time. The dynamics can only be fully reversible for a genuine equilibrium process for which the entropy production vanishes at all times. Moreover, issues linked to the "complexity" of the preparation of the initial state to be used in the forward dynamics (or the corresponding one associated with the time-reversed evolution) have to be considered (33). By providing an experimental assessment of the microscopic foundation of irreversibility (systematically beyond the linear response regime), our results both elucidate and quantify the physical origin of the arrow of time in the quantum setting of an isolated system.
