A Tractable Approach to Uplink Spectral Efficiency of Two-Tier Massive MIMO Cellular HetNets

Wen Liu, Student Member, IEEE, Shi Jin, Member, IEEE, Chao-Kai Wen, Member, IEEE, Michail Matthaiou, Senior Member, IEEE and Xiaohu You, Fellow, IEEE

Abstract—This letter investigates the uplink spectral efficiency (SE) of a two-tier cellular network, where massive multiple-input multiple-output macro base stations are overlaid with dense small cells. Macro user equipments (MUEs) and small cells with single user equipment uniformly scattered are modeled as two independent homogeneous Poisson point processes. By applying stochastic geometry, we analyze the SE of the multiuser uplink at a macro base station that employs a zero-forcing detector and we obtain a novel lower bound as well as its approximation. According to the simple and near-exact analytical expression, we observe that the ideal way to improve the SE is by increasing the MUE density and the base station antennas synchronously rather than increasing them individually. Furthermore, a large value of path loss exponent has a positive effect on the SE due to the reduced aggregated interference.

Index Terms—Massive MIMO, Poisson point process, small cells, spectral efficiency, stochastic geometry

I. INTRODUCTION

In the emerging 5G communication systems, massive multiple-input multiple-output (MIMO) and small cells are both regarded as critical components [1] and have been extensively studied in recent years. These two promising technologies can be combined when macro cells with massive MIMO base stations (BSs) are overlaid by dense small cells; such a deployment utilizes the excessive number of antennas at macro BS for managing interference meanwhile takes advantage of the smaller propagation distance in small cells to greatly improve the throughput performance of cell edge users and extend coverage [2].

In general, stochastic geometry provides a nature way of modeling the locations of users or BSs and such is particularly relevant to interference analysis [3]. Recent efforts [4,5] have focused mainly on deriving expressions for the outage capacity and approximated distribution of the signal-to-interference-and-noise ratio (SINR), typically by involving a Laplace transform in their final expressions. However, this mathematical technique blurs any engineering insights for network designers.

This paper considers a general two-tier cellular network model in which user equipments (UEs) and small cells are distributed as independent homogeneous Poisson point processes (PPPs). Given the analytical tractability of the PPP model, we derive a novel lower bound on the aggregate spectral efficiency (SE) and further obtain an approximated expression of this lower bound. With this concise expression, we can intuitively determine how the model parameters influence the aggregate SE of the complex two-tier model.

Notations: The expectation and probability are denoted by $\mathbb{E} [\cdot]$ and $\mathbb{P} [\cdot]$, respectively. $\mathcal{CN}(0, \sigma^2)$ represents the complex Gaussian distribution with zero mean and variance of $\sigma^2$, while $\| \cdot \|$ denotes the Frobenius norm.

II. SYSTEM MODEL

We consider a cellular network consisting of $B$ (can be extended to infinity over the whole plane) macro tier massive MIMO BSs equipped with $M$ antennas, which is overlaid with small cells (SCs) each equipped with $N$ antennas, as explicitly shown in Fig. 1. Single-antenna UEs scattered over both tiers can be classified into two categories, namely, macro UEs (MUEs) and small cell UEs (SUEs), which are served by the BSs and SCs, respectively. This paper focuses on the uplink aggregate SE with full frequency reuse in both tiers.

In the model of interest, BSs are located in the center of hexagonal cells, which can be approximated by a circular area for the sake of analytical tractability. The MUEs are randomly distributed in the range of the macro cell and can be modeled as a homogeneous PPP with density $\lambda_m$. Meanwhile, the SCs

Fig. 1. Illustration of a two-tier network deployment with massive MIMO macro cells overlaid by small cells.

Notations:
- $\mathbb{E} [\cdot]$ and $\mathbb{P} [\cdot]$, respectively.
- $\mathcal{CN}(0, \sigma^2)$ represents the complex Gaussian distribution with zero mean and variance of $\sigma^2$, while $\| \cdot \|$ denotes the Frobenius norm.
- $\Lambda$ is a Poisson point process.
- $\lambda_m$ is the density of macro cells.
- $\lambda_s$ is the density of small cells.
- $\sigma_m^2$ and $\sigma_s^2$ are the variances of MUE and SUE signals, respectively.
- $\gamma_m$ and $\gamma_s$ are the SINRs for MUE and SUE, respectively.
- $G_{mk}$ is the channel gain from macro BS $k$ to MUE $m$.
- $H_{sk}$ is the channel gain from macro BS $k$ to SUE $s$.

are modeled as a homogeneous PPP with density $\lambda_{SC}$. In addition, we assume that only one randomly distributed SUE is associated with each SC within its range in a resource block [2]. From the PPP property [6], we can easily deduce that the location of a SUE experiences an identical distribution with that of SCs, that is, the density of SUES $\lambda_s = \lambda_{SC}$. The radii of BSs and SCs are defined as $R_M$ and $R_S$, respectively. In addition, the BS has a disk guard zone of radius $R_G$, within which there are no UEs.

In the co-channel deployment, the $M \times 1$ received signal at the desired BS (i.e., the massive MIMO BS in cell 1) is

$$y = \sum_{b=1}^{B} G_b A_b^H x_b + \sum_{b=1}^{B} \Omega_b P_b^H z_b + n,$$

where $G_b \in \mathbb{C}^{M \times K_b}$, $\Omega_b \in \mathbb{C}^{M \times S_b}$ denote the propagation matrices of the MUEs and SUEs in cell $b$ to the desired BS and $K_b, S_b$ are the total numbers of MUEs, SUEs in cell $b$. A typical propagation coefficient, for instance, $g_{bsj}$, which defines the channel between the $i$th BS antenna in the $k$th cell and $j$th UE in the $i$th cell, can be modeled as $g_{bsj} = h_{bsj} \beta_{ij}$, where $h_{bsj} \sim \mathcal{CN}(0,1)$ denotes the independent and identically distributed (i.i.d.) fast fading coefficients. The factor $\beta_{ij}$, which represents large scale fading, is defined as $\beta_{ij} = \gamma_{ij}^{-1}$, where $\gamma_{ij}$ is the path loss exponent. The large scale fading is assumed to be invarient between the two ends regardless of antenna difference [7]. In addition, $A_b = \text{diag} \left( p_{b1}, p_{b2}, \ldots, p_{bK_b} \right)$ and $P_b = \text{diag} \left( p_{b1}^S, p_{b2}^S, \ldots, p_{bS_b}^S \right)$ are diagonal power matrices for MUEs and SUEs in cell $b$; $x_b$ and $z_b$ represent the column transmit vectors of the MUEs and the SUEs to their associated BSs in cell $b$; and $n$ models the complex additive white Gaussian noise whose entries are i.i.d. with $\mathcal{CN}(0,1)$. For ease of notation, the transmit symbols are normalized as $E[x_n x_n^H] = I_{K_b}$, $E[z_n z_n^H] = I_{S_b}$.

Under the assumption of perfect CSI of its serving UEs, the linear zero-forcing (ZF) receiver is employed at the BSs. The received signal after the ZF detector is $r = A^H y$, where the ZF detection matrix is $A = G_1 (G_1^H G_1)^{-1}$. Then, the detected signal of the $k$th MUE, which is equivalent to the $k$th element of $r$, can be further described as

$$r_k = \sqrt{p_{1k}^M} x_k + \sum_{b=2}^{B} \sum_{c=1}^{K_b} p_{bc}^M \alpha_{bc}^H G_{bc} x_{bc} + \sum_{b=1}^{B} \sum_{s=1}^{S_b} \sqrt{p_{bs}^S} \alpha_{k}^H \omega_{bs} z_{bs} + a_k^H n,$$

where $a_{bc}, \omega_{bs}$ are the $k$th, $c$th, and $s$th columns of $A, G_{bc}, \Omega_b$, respectively, and $p_{bc}^M$ denotes the uplink power of the $c$th UE in the $b$th cell. In this paper, we apply the Channel Inversion power control scheme, i.e., $p_{bc}^M = \beta_{bc} r_{bc}^{-1}$, to compensate for large scale fading. This power control scheme is widely used since it eliminates the near-far effect and guarantees the performance of cell edge UEs, only requiring long-term information [4]. Therefore, the SINR of the $k$th MUE is written as

$$\text{SINR}_k = \frac{\sum_{b=1}^{B} \sum_{c=1}^{K_b} \frac{p_{bc}^M}{\beta_{bc}} |\alpha_{bc}^H|^2}{\sum_{b=1}^{B} \sum_{s=1}^{S_b} \frac{p_{bs}^S}{\beta_{bs}} |\alpha_{k}^H|^2 + \|a_k^H n\|^2}.$$  

(3)

From (3), we observe that the MUE interference originates from inter-cells, whereas SUE interference originates from both intra- and inter-cells. The average SE of the $k$th MUE can be obtained through

$$R_k = \mathbb{E} \left[ \log_2 (1 + \text{SINR}_k) \right],$$

(4)

where the expectation is taken over $a_k^H, g_{bc}^H, \text{and } \omega_{bs}$.

III. SPECTRAL EFFICIENCY ANALYSIS

The average aggregate SE of MUEs in the desired cell is defined as

$$R = \sum_{k=0}^{\infty} \mathbb{E} \left[ \sum_{k=1}^{K_1} \log_2 (1 + \text{SINR}_k) | \kappa = K_1 \right] \cdot P(\kappa = K_1),$$

(5)

where $\kappa$, subject to a Poisson($\mu_m$) distribution, denotes the random variable of the MUE number in the desired cell and $\mu_m = \lambda_m A_{BS}$ denotes the mean number of MUEs, where $\lambda_m$ is the MUE density and $A_{BS}$ is the area of the macro cell. By substituting $P(\kappa = K_1) = \frac{e^{-\mu_m} \mu_m^K}{K_1!}$ into (5), we derive

$$R = \sum_{K_1=0}^{\infty} K_1 \mathbb{E} \left[ \log_2 (1 + \text{SINR}_k) | \kappa = K_1 \right] \cdot \frac{\mu_m^K e^{-\mu_m}}{K_1!},$$

(6)

where we can extract $K_1$ from the expectation due to the fact that MUEs are generated from the same PPP.

To calculate the aggregate SE of MUEs, we have to determine the SE of a typical user, as expressed in (4). However, this task is extremely difficult to accomplish. As such, we seek a lower bound on the SE and its approximation in the following subsections.

A. Lower Bound on the Spectral Efficiency

First, we rewrite (3) into a concise form

$$\text{SINR}_k = \frac{1}{\sum_{i=1}^{N_1} \frac{p_{i1}^M |\alpha_{i1}^H|^2}{\|a_i^H|^2} + \sum_{j=1}^{N_2} \frac{p_{j1}^S |\alpha_{j1}^H|^2}{\|a_j^H|^2} + 1} \|a_k^H n\|^2,$$

(7)

where, for simplicity, we have reduced the subscripts of $p_{bc}^M, p_{bc}^S, g_{bc}^H, \omega_{bs}$, and let the total number of MUE and SUE interferers be $N_1 = \sum_{b=2}^{B} K_b$ and $N_2 = \sum_{b=1}^{B} S_b$, respectively. By applying Jensen’s inequality to $\mathbb{E} [\log_2 (1 + \text{SINR}_k) | \kappa = K_1]$ and using the fact that $I$ and $\chi_0$ are independent, we obtain

$$\mathbb{E} [\log_2 (1 + \text{SINR}_k) | \kappa = K_1] \geq \log_2 \left( 1 + \frac{1}{\mathbb{E} [(I + 1)] \mathbb{E} [\chi_0] / \overline{\rho} \right),$$

(8)

where the condition term is omitted for simplicity.

Assume that a UE is uniformly distributed in the circular area with radius $R$ but excluded from the guard zone with radius $R_G$. Then, the probability density function (pdf) of the distance $r$ from UE to the center is given by

$$f(r) = \begin{cases} \frac{2r}{R^2 - R_G^2}, & r \in (R_G, R], \\ 0, & \text{others}. \end{cases}$$

(9)

Adopting this distance pdf, we have the following theorem.

Theorem 1: The lower bound on the aggregate SE in the desired cell is given below and $c_{GS} = \frac{R_G}{R}$, $c_{GM} = \frac{R}{R_M}$

$$R_{\text{lower}} = \sum_{K_1=0}^{\infty} K_1 \frac{\mu_m^K e^{-\mu_m}}{K_1!} \log_2 \left( 1 + \frac{M - K_1}{I_1 + I_2 + 1} \right).$$

(10)
where $I_1 = 4\pi \lambda_m \frac{R^2}{(\alpha^2 - 4)} (1 - \frac{1}{\alpha^2})$ and $I_2 = 4\pi \lambda_m \frac{R^2 \gamma^2}{\alpha^2 - 4}$.

Proof: See Appendix A.

Theorem 1 shows how the aggregate SE scales with the system parameters, namely, the MUE density $\lambda_m$ ($\mu_m$ can also represent MUE density when area is a constant), the SUE density $\lambda_s$, BS antenna number $M$, and the path loss exponent $\alpha$. These parameters will be discussed in detail in the next subsection by evaluating a more simplified expression.

B. Approximated Lower Bound Analysis

The lower bound expression (10) consists of the sum of infinite series, which is still difficult to evaluate. Alternatively, we notice that the variable of the summation $K_1$ only appears in the logarithmic function in the form of $M - K_1$. In the model of interest, we have $M \gg K_1$. Therefore, an approximation of the lower bound can be obtained by disregarding $K_1$, which results in the following corollary.

Corollary 1: The lower bound on the aggregate SE can be approximated by

$$R_{\text{lower}} \approx \hat{R}_{\text{lower}} = \mu_m \log_2 \left( 1 + \frac{M}{\frac{4\mu_m}{\alpha^2 - 4} + 4\pi \lambda_s \frac{R^2 \gamma^2}{\alpha^2 - 4} + 1} \right).$$

(11)

Proof: As $M \gg K_1$, $c_{GM} \ll 1$, we omit $K_1$, $c_{GM}$ in (10) and obtain the final result with some simple algebra.

The approximation by disregarding $K_1$ renders a closed-form expression without infinite series. This expression can be extremely close to $R_{\text{lower}}$ when $M$ becomes large. With the simple and clear expression of (11), we present some insights into properties of this two-tier network.

Corollary 2: As $\mu_m \to \infty$, which means that the total number of MUEs in each macro cell approaches infinity, the approximation of the lower bound is given by

$$\left( \hat{R}_{\text{lower}} \right)_{\mu_m \to \infty} = \frac{M}{4} (\alpha^2 - 4) \log_2 e.$$

(12)

Proof: Applying the fact that $\lim_{x \to -\infty} (1 + \frac{1}{3})^x = e$ to (11), we obtain the desired result.

Remark 1: Several parameters in (11) provide opportunities to enhance the aggregate SE, such as increasing the MUE density. However, Corollary 2 suggests that the aggregate SE converges to a certain value in terms of $M$ and $\alpha$ when we densify MUE without constraint, which, however, diminishes the average SE of each MUE. Since dense deployment causes heavy interference, a tradeoff exists between the average SE and the aggregate SE. Therefore, after ensuring a certain average SE, the MUE density can be increased as far as possible to obtain the highest aggregate SE.

Remark 2: From (11), the aggregate SE can also be improved by increasing $M$. To this end, we take the derivative of (11) w.r.t. $M$ and obtain

$$\tau_M = \frac{d\hat{R}_{\text{lower}}}{dM} = \mu_m \log_2 e \frac{\frac{4\mu_m}{\alpha^2 - 4} + 4\pi \lambda_s \frac{R^2 \gamma^2}{\alpha^2 - 4} + 1 + M}{4 (\alpha^2 - 4) \log_2 e}.$$

(13)

We find $\tau_M \to 0$ as $M \to \infty$. This means that if $\mu_m$ and the other parameters are fixed, the slope of the aggregate SE decreases to zero. Therefore, by merely increasing the number of BS antennas we cannot avail of a sustainable growth of the aggregate SE because $M$ appears only inside the logarithm in (11). By reforming (13), we find that the slope is determined by the ratio $\frac{M}{\mu_m}$. Therefore, if $\mu_m$ increases together with $M$ to infinity while keeping a fixed ratio $\frac{M}{\mu_m} = c$, the slope does not converge to 0 but to

$$\tau_M \to \frac{\log_2 e}{\alpha^2 - 4} + c.$$

(14)

This result supports the promising benefit of massive MIMO topologies in two-tier cellular networks.

IV. NUMERICAL RESULTS

We consider a conventional seven-cell cellular network model. The parameters used in the simulations are summarized in Table I. All simulation points have been averaged over 100,000 different channel realizations and UE, SC locations.

**Fig. 2.** The aggregate SE versus mean number of MUEs per cell with $\alpha = 4$ and $M = 500$ satisfying $M \gg K_1 (\mu_m)$.

**Fig. 3.** The aggregate SE versus BS antenna number for different $\mu_m$ with $\alpha = 4$.

Fig. 2 illustrates the aggregate SE versus the mean number of MUEs per cell. The lower bound and its approximation are extremely tight with the Monte Carlo simulations, and the approximation is closer than the lower bound. The reason is that disregarding $K_1$ in (11) caused the approximation to be slightly larger than the lower bound, resulting in a more precise approximation of the lower bound. In addition, as shown in
the expectation of the aggregation interference. 

The proposed approach to SE can also be applied to the SE of SUEs, which will enable us to obtain the total SE of two-tier networks. The parameters influence the aggregate SE of this complex model.

Therefore, the expectation of the aggregation interference is

\[ \mathbb{E} \left[ \hat{g}_i^2 \right] = \tilde{\beta}_i = \tilde{r}_i^{-\alpha} \quad \text{and} \quad \mathbb{E} \left[ \tilde{\omega}_j^2 \right] = \tilde{\beta}_j = \tilde{r}_j^{-\alpha}, \]

where \( \beta \) represents the large scale fading coefficient. In addition, \( \hat{a}_k = \frac{a_k^H}{\|a_k\|} \) can be regarded as a location vector with \( \|\hat{a}_k\|^2 = 1 \). Thus, with the independent nature between \( \hat{a}_k \) and \( (g_i, \omega_i) \), together with the property that the sum of independent Gaussian variables is also Gaussian, we have \( \hat{g}_i \sim \mathcal{CN}(0, \hat{\beta}_i) \) and \( \tilde{\omega}_j \sim \mathcal{CN}(0, \tilde{\beta}_j) \). In particular, we have

\[ \mathbb{E} \left[ \hat{g}_i^2 \right] = \hat{\beta}_i = \hat{r}_i^{-\alpha} \quad \text{and} \quad \mathbb{E} \left[ \tilde{\omega}_j^2 \right] = \tilde{\beta}_j = \tilde{r}_j^{-\alpha}, \]

V. CONCLUSION

This study investigated the aggregate uplink SE of MUEs in a two-tier network, and a novel lower bound, as well as a closed-form approximation, using tools of stochastic geometry. We also obtained new quantitative insights on how the system parameters influence the aggregate SE of this complex model. The proposed approach to SE can also be applied to the SE of SUEs, which will enable us to obtain the total SE of two-tier networks in the future.

Appendix A

Proof of Theorem 1

From (8), the problem of deriving the lower bound is now reduced to evaluating \( \mathbb{E} \left[ I \right] \) and \( \mathbb{E} \left[ \chi_0 / p^{MI}_{1k} \right] \). We first deal with the expectation of the aggregation interference. Thanks to Slivnyak’s theorem [3], we can model MUE interferers as a homogeneous PPP \( \Phi_m \) and SUE interferers as another independent homogeneous PPP \( \Phi_s \) without changing the density. From (7) and (8), we notice that the power, i.e., \( p_i \), and the interfering channel vector are statistically independent. Therefore, the expectation of the aggregation interference is given by

\[ \mathbb{E} \left[ I \right] = \mathbb{E} \left[ \sum_i \mathbb{E} \left[ p_i^M \right] \mathbb{E} \left[ \hat{g}_i^2 \right] \right] + \mathbb{E} \left[ \sum_j \mathbb{E} \left[ p_j^S \right] \mathbb{E} \left[ \tilde{\omega}_j^2 \right] \right], \]

where \( \hat{g}_i = \frac{a_k^H g_i}{\|a_k\|} \) and \( \tilde{\omega}_j = \frac{a_k^H \omega_j}{\|a_k\|} \). Note that the entries of \( g_i \) and \( \omega_j \) are i.i.d. random variables with \( \mathcal{CN}(0, \beta) \),

Fig. 2, according to the analysis of Corollary 2, the curves tend to flatten and will saturate when \( \mu_m \) becomes large enough.

Fig. 3 shows the aggregate SE performances with different \( \mu_m \) when the BS antenna number becomes large. We observe that the aggregate SE can be enhanced by increasing the BS antennas for all \( \mu_m \). The aggregate SE grows faster for the setting with the larger \( \mu_m \), as predicted by (14).

Fig. 4 depicts the aggregate SE as a function of the path loss exponent \( \alpha \), which typically ranges from 3 to 5. Interestingly, a larger \( \alpha \) leads to a higher aggregate SE and a tighter bound. From (3), it can be observed that the useful signal power decreases less slowly than the aggregation of interference with increasing \( \alpha \). Therefore, the aggregate SE for the scenario with higher path loss exponent outperforms that with a lower one.

REFERENCES
