Abstract

A glasshouse pot experiment and a laboratory leaching column experiment were conducted to study the EDTA enhancement of the mobility and phytoextraction of heavy metals and the potential for leaching of metals during the phytoextraction process. Addition of EDTA (disodium salt, 3 mmol kg⁻¹) to pots of a paddy soil (an Fe-accumulic Gleyi-Stagnic Anthrosol) historically polluted with Cu and experimentally spiked with Zn, Pb and Cd significantly enhanced the mobilities of soil Cu and Pb but not of Zn and Cd. EDTA increased shoot Cu and Pb concentrations in Indian mustard (Brassica juncea) plants growing in the soil but the resulting offtakes were low and a sequence of at least 200 crops would be required to remediate the soil. Addition of oxalic, citric or malic acid to soil at the same rate (3 mmol kg⁻¹) had virtually no effect on uptake of the metals by Indian mustard. EDTA addition led to elevated soil solution concentrations of TOC, Cu, Zn, Pb and Cd for about 1 month. Rainfall after EDTA application, as simulated by the column leaching experiment, increased the concentrations of Cu, Zn, Pb and Cd linearly in leachate with increasing EDTA dosage (0–12 mmol kg⁻¹). EDTA addition also led to losses of soil macronutrients including Fe. About 68% of the added EDTA tended to chelate soil Cu, Zn, Pb and Cd and the remaining 32% was chelated with and leached other ions. Total Cu, Zn, Pb and Cd losses were significantly correlated with EDTA dosage. The low shoot offtakes of Pb and Cu and the risk of groundwater pollution as EDTA remains active for several weeks make chelate-enhanced phytoremediation with Indian mustard unsuitable for this soil, especially during periods of high rainfall.

Keywords: Heavy metals; Phytoremediation; EDTA; Organic acids; Brassica juncea; Leaching risk

1. Introduction

Soils can be contaminated with heavy metals from various human activities including mining, smelting and metal treatment operations, vehicle emissions and deposition or leakage of industrial wastes. Because of the potential toxicity and high persistence of heavy metals, the clean up of contaminated soils is one of the most difficult tasks for environmental engineering. A number of ‘ex situ’ and ‘in situ’ techniques have been developed to remove heavy metals from contaminated soils.

The technique of soil washing has been used to remove metals from the solid phase to a liquid matrix. Metal extraction can be achieved with organic
or inorganic acids (Wasay et al., 1998, 2001; Davis et al., 1998). EDTA is the most effective and popular reagent because it is a strong, recoverable and relatively biostable chelating agent that has potential for soil remediation applications (Hong et al., 1999). The concentration and pH of a reagent influence the washing effect. When excessive EDTA is present, the amounts of cations extracted are usually pH-independent, but when EDTA is in short supply, the amounts of cations extracted show a complex behavior in relation to pH (Ghestem and Bermond, 1998). The mode of EDTA addition is also a significant factor controlling the behavior of metal leaching (Sun et al., 2001). In Ca-rich soil, the simultaneous dissolution of calcite was found to consume most of the available EDTA (Papassiopi et al., 1999), and adding CaCl₂ or KOH was recommended (Heil et al., 1999), or using the calcium salt of EDTA instead of the common sodium salts (Theodoratos et al., 2000).

Phytoremediation of heavy metal contaminated soil is a developing technology that aims to extract or inactivate metals and it has attracted much attention because it is an environmentally friendly and relatively cheap technique (McGrath, 1998; McGrath et al., 2002). There are two basic strategies under development. The first is the use of hyperaccumulator plants that have the capacity to hyperaccumulate heavy metals, and the second is chemical chelate-enhanced phytoextraction (Salt et al., 1998). The major problem hindering plant remediation efficiency is that some of the metals are immobile in soil and their availability and phytoextraction rate are limited by solubility and diffusion to the root surface. Chemical enhancements have been used to overcome this problem (Blaylock et al., 1997; Huang et al., 1997; Ebbs and Kochian, 1997; Wu et al., 1999; Epstein et al., 1999), and the most promising application of this technology is for the remediation of Pb-contaminated soils using Indian mustard (Brassica juncea (L.) Czern) in combination with EDTA (Blaylock, 2000). Despite the possible usefulness of this technology, some concerns have been expressed regarding the potential risk of leaching of metals to groundwater. EDTA significantly elevated the extractability of Zn and Ni in unpolluted and metal-amended soils and increased the mobility of Zn and Ni (Li and Shuman, 1996). EDTA mobilized metals rapidly, and subsequently their concentrations decreased slowly. High concentrations of heavy metals in the soil solution could pose an environmental risk in the form of groundwater contamination (Cooper et al., 1999; Lombi et al., 2001). Romkens et al. (2002) reported that EDTA, which has a high specific affinity for Cd, enhanced metal solubility, but plant metal uptake did not increase accordingly and shoot and root biomass production was depressed. Furthermore, EDTA greatly reduced the number of microbivorous nematodes and enhanced metal leaching in a lysimeter study. Thus, potential environmental risk should be considered when chelate enhancement is used to improve phytoremediation efficiency.

Some studies have indicated that EDTA–metal complexes are resistant to microbial degradation. EDTA was found to be slowly biodegraded to CO₂ in soil, with only 6.7% degraded after 4 weeks and a lower rate of degradation in the subsoil than in surface soil (Tiedje, 1975). Means et al. (1980) reported that the EDTA degradation rate was not rapid enough, even under optimal laboratory conditions, to preclude concern about its release to the environment. However, Belly et al. (1975) showed that 28% of the acetate-2-C and 30% of the ethylene position of ammonium ferric chelate of ¹⁴C-EDTA were recovered as ¹⁴CO₂ after 5 days. Little work has been done on the dynamics of EDTA degradation, and the extent of its limitation on mobilization of heavy metals is still unknown.

Experiments using soils artificially spiked with heavy metals may result in high performance of phytoextraction effects (Kumar et al., 1995) because of the high availability of heavy metals in artificially spiked soils. However, in sites with long-term heavy metal contamination, the phytoextraction effect on Pb was also extremely high (Huang et al., 1997). In the present paper, we report a glasshouse pot experiment and a laboratory leaching column experiment in which we studied a soil with long-term Cu contamination that was spiked with Zn, Cd and Pb salts, Indian mustard (B. juncea) was used in the pot experiment. The aim was to investigate: (1) EDTA enhancement of mobility and phytoextraction of both historical and newly spiked heavy metals; (2) the progress of EDTA degradation and its effect on the mobility of the heavy metals; (3) the potential for leaching of heavy metals after EDTA addition to the soil with the consequent potential leaching risk during the phytoextraction process.
2. Materials and methods

2.1. Soil sampling and spiking with Zn, Cd and Pb

Soil (an Fe-accumulic Gleyi-Stagnic Antrosol) was taken from the surface layer (0–10 cm) of a paddy field in Tai Lake Region, Jiangsu province, China, with a previous history of irrigation with Cu-rich wastewater. The soil is a clay loam with a pH (in water) of 6.3. The soil was air-dried and spiked with 500, 500 and 50 mg kg\(^{-1}\) of Zn, Pb and Cd by dissolving the nitrate salts in 150 ml distilled water and mixing thoroughly into the soil to adjust the moisture content to about 40% of water holding capacity (WHC). Thorough mixing of the soil would have been much more difficult at higher soil moisture contents. The spiked soil was placed in a glasshouse for 1 month to allow it to equilibrate and to promote adsorption of the added metals. The soil was then air dried and sieved through a 2 mm nylon mesh for chemical analysis and use in the two experiments. Soil total (HNO\(_3\)–HClO\(_4\)–HF digestion) Cu, Zn, Pb and Cd concentrations were 169, 518, 492 and 45.7 mg kg\(^{-1}\), respectively.

2.2. Pot experiment

The treatments comprised the following amendments (all made at the rate of 3 mmol kg\(^{-1}\) soil on oven dry basis): (1) control with no amendment (CK); (2) EDTA disodium salt (EDTA); (3) oxalic acid (OA); (4) citric acid (CA); (5) malic acid (MA). Air-dried soil equivalent to 1.5 kg (oven dry basis) was placed in each plant pot (15 cm top and 11 cm bottom diameters, and 12 cm high). NH\(_4\)NO\(_3\) and KH\(_2\)PO\(_4\) were applied as basal fertilizers at the rates of 0.43 and 0.33 g kg\(^{-1}\), respectively. Nine seeds of Indian mustard (\textit{B. juncea} (L.) Czern, accession: PI 426308, origin: Pakistan) were sown in each pot and thinned to three seedlings 13 days after sowing. All pots were adjusted daily by weight to 70% water holding capacity (WHC) with distilled water to maintain vigorous plant growth. There were three replicates of each treatment in a fully randomized design. EDTA and the other organic acid amendments were added to the pots 40 days after sowing and plants were harvested after 52 days. Soil solution samples were collected from the extra control and EDTA pots 6, 12, 29 and 52 days after the EDTA was applied to the soil. Each soil solution sample was separated into several aliquots for analysis of pH, total organic carbon (TOC) content, and total and organic chelate combined Cu, Zn, Pb and Cd complexes concentrations by the methods of Holm et al. (1995). The aboveground parts of Indian mustard were washed with tap water and rinsed with distilled water, oven dried at 80 °C, ground and digested with 3:2 (v/v) nitric/perchloric acids. Fresh soil sub-samples were also collected to determine 1 M NH\(_4\)NO\(_3\)-extractable Cu, Zn, Pb and Cd. Metal analysis was performed using a PQEMS II (Thermo Jarrell Ash) inductively coupled plasma-atomic emission spectrometer (ICP-AES). Data are presented as the means of three replicates together with standard errors.

2.3. Leaching column experiment

A leaching column experiment was carried out to investigate the effects of the volume and pH of leaching water on soil heavy metals and other elements leaching from the ‘arable’ layer under different EDTA dosages in phytoremediation enhancement. The treatments are shown in Table 1 for clarity. A layer of fine sand (washed with HCl, followed by tap water and then distilled water) and one sheet of 0.15 mm nylon solution. EDTA and the other organic acid amendments were added to the pots 40 days after sowing and plants were harvested after 52 days. Soil solution samples were collected from the extra control and EDTA pots 6, 12, 29 and 52 days after the EDTA was applied to the soil. Each soil solution sample was separated into several aliquots for analysis of pH, total organic carbon (TOC) content, and total and organic chelate combined Cu, Zn, Pb and Cd complexes concentrations by the methods of Holm et al. (1995). The aboveground parts of Indian mustard were washed with tap water and rinsed with distilled water, oven dried at 80 °C, ground and digested with 3:2 (v/v) nitric/perchloric acids. Fresh soil sub-samples were also collected to determine 1 M NH\(_4\)NO\(_3\)-extractable Cu, Zn, Pb and Cd. Metal analysis was performed using a PQEMS II (Thermo Jarrell Ash) inductively coupled plasma-atomic emission spectrometer (ICP-AES). Data are presented as the means of three replicates together with standard errors.

mesh were inserted into each PVC column (3.3 cm i.d. and 25 cm in length). Air dried soil (historically contaminated with Cu and spiked with Zn, Pb and Cd as described above) equivalent to 214 g (oven dry basis) was then added in small portions. The appropriate quantity of EDTA disodium salt was dissolved in 40 g distilled H2O and added to the soil surface in the columns to give a soil moisture content of about 40% WHC, and the following day the columns were placed in plastic saucers containing distilled water to maintain moisture content from the base. The columns were kept at room temperature 3 days before leaching. There were three replicates of each treatment. Twenty ml or 40 ml of water at a specific pH value were added to the top of each column by syringe at a flow rate of 4 ml h−1. This comprised the first leaching event. The subsequent water application event of was made when no more leachate was produced. The soil hydraulic conductivity decreased with leaching water volume, and so the intervals of water addition were also lengthened. The aliquots of water (either 20 or 40 ml) were applied to the columns on 12 occasions over the course of the leaching experiment, which had a total duration of 48 days. The pH of the water applied to some of the columns was adjusted using a mixture of dilute nitric and sulfuric acids to include pH values of pH 4.3 and 3.0 in order to simulate rainwater pH values found in the field. Each leachate was collected in a plastic bottle, weighed, and then separated into several portions for measurement of pH and determination of total organic carbon (TOC) and total Cu, Zn, Pb, Cd, Fe, Ca and Mg concentrations. After the experiment, soil was removed from the columns, air dried, ground to <0.25 mm, and analyzed to investigate changes in total metal concentrations under different doses of EDTA, leaching water volumes and pH values. Metals were determined using a Thermo Jarrell Ash ICP-AES. TOC was determined using a Shimadzu 500A TOC Analyzer, and soil solution pH was measured using a pH meter. Data presented are means of three replicates together with standard errors.

3. Results and discussion

3.1. Availabilities of soil heavy metals in pot experiment

NH4NO3 is a weak extractant that extracts mainly the water-soluble and part of the exchangeable fraction of metals. The soil had been contaminated with Cu for more than 3 years before the pot experiment was conducted, hence the NH4NO3-extractable fraction was only 0.70 mg kg−1 in the absence of EDTA (Table 2). When 3 mmol kg−1 of EDTA was added, NH4NO3-extractable Cu increased to 52.7 mg kg−1, more than a 30-fold increase over the control value. However, soil NH4NO3-extractable Cu did not increase when oxalic, citric or malic acid was applied at the same rate (Table 2). Lead is readily adsorbed by soil colloids, hence its mobility is always very low and this is considered to be the main factor restricting the phytoremediation of Pb-contaminated soils. Thus, although the soil was newly spiked with Pb in this experiment, the NH4NO3-extractable Pb in non-EDTA-amended soil after plant growth was only 4.7 mg kg−1. EDTA addition significantly increased soil NH4NO3-extractable Pb to 26.6 mg kg−1, almost a six-fold increase compared with the unamended control. The three organic acids again had no effect on soil NH4NO3-Pb. In contrast, Zn and Cd are highly mobile in the soil, and their NH4NO3-extractable

concentrations in the unamended control soil were 138 and 14 mg kg\(^{-1}\), representing 27 and 30% of soil total and spiked Zn and Cd. EDTA addition increased soil extractable Zn or Cd only slightly compared with its large influence on Cu and Pb.

### 3.2. Plant growth and heavy metal uptake

There were no visible symptoms of heavy metal toxicity in Indian mustard during germination and growth. However, 2–4 days after EDTA addition into the soil there were numerous brown dots on the leaves, and the whole leaf became yellow and died slowly, indicating phytotoxicity of EDTA metals. There was no clear effect of the three organic acids on growth of Indian mustard. The aboveground yields were slightly lower in the EDTA treatment, but the differences among the five treatments were not significant (Table 3).

Table 3 also shows the Cu, Zn, Pb and Cd concentrations in Indian mustard shoots. Applied EDTA significantly increased both the mobility of soil Cu and the concentrations of Cu in the shoots of Indian mustard, whereas the three organic acids did not show this effect. EDTA also increased shoot Pb concentrations but, in common with the three organic acids, had little effect on shoot Zn and Cd concentrations.

Phytoextraction efficiency is related to both plant metal concentration and dry matter yield. Thus, the ideal plant species to remediate a contaminated site should be a high yielding crop that can both tolerate and accumulate the target contaminants. Indian mustard has been demonstrated to accumulate moderate levels of Pb, Zn and Cu (Kumar et al., 1995; Ebbs and Kochian, 1997). When synthetic chelate was used, concentrations of 1.5% in the shoots of *B. juncea* were obtained from soils containing 600 mg Pb kg\(^{-1}\) (Blaylock et al., 1997). The accession of Indian mustard used in the present experiment (PI 426308) is the same variety that was used by Ebbs and Kochian (1997) and it also showed good metal accumulation performance. Table 3 shows that shoot Cu uptake by plants growing in soil treated with EDTA was significantly higher than that of the unamended control, whereas the three organic acids had no effect on shoot Cu uptake. Lead uptake in the EDTA treatment was nearly three-fold higher than the control. Although shoot Pb uptake was also enhanced by addition by oxalic, citric and malic acids, the increases were smaller than those produced by EDTA. Despite the enhancement of Pb and Cu uptake by Indian mustard shoots, in the added EDTA treatment, uptakes of Cu, Zn, Pb and Cd were only 0.11, 0.64, 0.02, 0.39%, respectively, of the soil total Cu, Zn, Pb or Cd. These offtakes of the metals would not be adequate for practical remediation of the paddy soil. To achieve soil cleanup of this contaminated soil, a sequence of 53, 205, 6088, or 255 crops would be required.

### 3.3. Soil solution TOC dynamics and EDTA degradation

Fig. 1a shows the TOC dynamics in the soil solution in the pot experiment. Six days after EDTA was applied the soil solution TOC in the EDTA treatment was 651 mg l\(^{-1}\), 746% of the control. Six days later the soil solution TOC had decreased by 45.3% to only 356 mg l\(^{-1}\) but was still higher than the control. Soil solution TOC decreased quickly with time; on the 29th day after EDTA application it was only 17.2% of the value on the 6th day, and there was no difference.
between days 52 and 29 even though it remained higher than the control.

Soil solution Cu in the pot experiment was markedly enhanced by EDTA addition (Fig. 1b). On the 6th day the Cu concentration was 64.1 mg l\(^{-1}\) in the EDTA treatment but only 0.08 mg l\(^{-1}\) in the control. On day 29, soil solution Cu decreased to 6.25 mg l\(^{-1}\), but was still higher than the control. From days 29–52 the soil solution Cu concentration remained at a low level but was much higher than the control. The dynamics of soil solution Zn, Pb and Cd concentrations were similar to those of Cu (Fig. 1c–e). The Pb concentration in the soil solution was also higher in the EDTA treatment than the control throughout the experiment, but after day 29 there were no differences in Zn and Cd. These results may be attributed to the contamination of the soil with Cu-rich wastewater more than 3 years before sampling. Thus a substantial proportion of soil Cu may...
have combined with immobile soil constituents over this time period and some of this Cu may have been re-mobilized by EDTA. The soil was spiked with Zn and Cd 1 month before the experiment and their mobilities remained high. Lead would have been readily adsorbed by soil colloids and other soil components, and its activity was always very low, so that EDTA increased the activity of Pb much more than Zn or Cd. This is considered to be the reason why EDTA can enhance Pb phytoextraction efficiency (Blaylock et al., 1997; Huang et al., 1997; Cooper et al., 1999). The organic chelate combined metal-complexes fraction is the portion chelated by soil organic matter and the added EDTA, and much of this can be considered to be mobile fraction. Fig. 1 shows that the heavy metals in the soil solution were mainly metal-complexes, especially when EDTA was used. This agrees with Lombi et al. (2001) who found that most of the heavy metals in soil pore waters were complexed by EDTA. Total amount and heavy metal-complexes were lower on the day 29 than on day 52, possibly because of an increase in soil organic matter and EDTA degradation and the appearance of a CO$_2$ emission peak (Fig. 2f).

EDTA disappearance may be due to biodegradation, chemical degradation, soil sorption and evaporation (Means et al., 1980). EDTA may have chelated with soil Cu, Zn, Pb and Cd and then enhanced the mobility of soil heavy metals in the long term. This may be why soil solution total and non-labile Cu, Zn, Pb and Cd remained high while TOC decreased to a very low level. Disappearance of EDTA in our pot experiment was faster than reported by Tiedje (1975) but slower than that observed by Means et al. (1980). Differences in EDTA disappearance may be due, at least in part, to different experimental conditions and soil types.

3.4. Effect of EDTA dosage on leaching of soil heavy metals

In the leaching column experiment rainfall processes were simulated after EDTA was used as a chelate to enhance phytoextraction efficiency. Fig. 2a shows the leachate TOC concentration dynamics. In the treatment consisting of 20 ml leaching aliquots of water, the leachate from the first leaching event from controls and columns treated with 3, 6 and 12 mmol kg$^{-1}$ leachate had TOC concentrations of 1131, 1870, 2540 and 4603 mg l$^{-1}$, showing increasing TOC with increasing EDTA dosage. Leachate TOC decreased quickly with leaching time and after the seventh leaching event (19 days from the start of the experiment), leachate TOC in EDTA treatments 0, 3, 6 and 12 mmol kg$^{-1}$ were only 199, 340, 515 and 684 mg l$^{-1}$.

Fig. 2 shows the Cu, Zn, Pb and Cd dynamics in the leachates. At the first event the Cu concentration in the control was only 0.57 mg l$^{-1}$ and with the three increasing EDTA addition levels leachate Cu increased with values of 60.6, 106.0 and 222 mg l$^{-1}$ (Fig. 2b). Thus, leachate Cu concentration increased by 100–400 folds. Leachate Cu concentration decreased quickly with leaching time and at the seventh event there was no difference among the treatments, a similar trend to leachate TOC. Linear correlation analysis showed that between the first and seventh leaching events there was a strong relationship between leachate TOC and Cu concentration ($r = 0.93, n = 16, P < 0.01$). This indicates that soil Cu was mainly chelated by the EDTA and then moved out from the ‘arable’ layer to the deep layers of the soil profile. This agrees with the soil solution metal dynamics results obtained in the pot experiment in which the soil solution Cu was mainly combined (complexed) with EDTA and other soil organic chelates (Fig. 1). Concentrations of Zn (Fig. 2c), Pb (Fig. 2d) and Cd (Fig. 2e) in the column leachates showed trends similar to those of Cu.

Fig. 2f shows that the leachate Fe concentration was very high when EDTA was added and increased with increasing EDTA dosage. Calcium and Mg concentrations were very high at the first leaching event and were much higher in the controls receiving no EDTA than in those to which EDTA was added (Fig. 2g and h). Spiking the soil with Zn, Pb and Cd resulted in high concentrations of exchangeable (and therefore high availability of) Ca and Mg with consequent high concentrations in leachate. However, EDTA addition increased soil Cu, Zn, Pb and Cd activities and decreased soil Ca and Mg mobility somewhat, and this resulted in low Ca and Mg in the leachate. Leachate Ca and Mg concentrations decreased quickly and at the second leaching event, the highest EDTA (12 mmol kg$^{-1}$) treatment had the lowest Ca and Mg concentrations and there was no difference among the other three treatments. This indicates that soil Ca and Mg were very mobile and likely to be leached quickly. This may explain the rapid loss in soil hydraulic conductivity.
Fig. 2. Effect of EDTA on leachate (a) TOC content and (b) Cu, (c) Zn, (d) Pb, (e) Cd, (f) Fe, (g) Ca and (h) Mg concentrations in the column leaching experiment; bars: ±S.E.
reported by Sun et al. (2001). Besides the leaching of Cu, Zn, Pb and Cd, EDTA addition may also have led to losses of soil macronutrients including Fe, Ca and Mg (Wasay et al., 1998). Our results did not agree with those of Wasay et al. (1998), perhaps because the soluble and the easily exchangeable fractions of soil Ca and Mg had already been leached from our paddy soil by long-term irrigation in the field.

3.5. Effects of leaching water volume and pH on movement of heavy metals

When EDTA was added to the soil at the rate of 3 mmol kg\(^{-1}\), the soil total organic carbon concentration was very high, mainly due to the EDTA. Thus, at the first leaching event the leachate TOC concentration was very high. Leachate TOC was lower in columns to which 40 ml of water were applied at each leaching event compared with 20 ml (Fig. 3). Leachate TOC decreased with leaching time, but leachate TOC concentration was still different between the two leaching water aliquot treatments. By the seventh event there was little soluble C remaining in the soil, consequently there was no difference between the two treatments. Leachate Cu contents again showed similar dynamics to TOC. At the first leaching event the Cu ions were readily desorbed by EDTA so that there was no difference between the two leaching water volume treatments (Fig. 3). Leachate Cu decreased with the increasing leaching time and the difference between the two leaching water volume treatments widened until at the fourth leaching event the two treatments were different. This may have been due to decreasing soil EDTA concentration as leaching proceeded over time. On the other hand, soil Cu adsorbed on soil colloids may have become more resistant to exchange and therefore less soluble. EDTA additions of 6 and 12 mmol kg\(^{-1}\) showed similar effects on leachate Cu concentrations (decreasing trends: data not shown). The effects of leaching water volume on leachate Zn, Pb and Cd dynamics were similar to those on Cu dynamics (data not shown).

There was no significant difference among the three rainwater pH values on leachate concentrations of heavy metals or macronutrients in the short time frame of our experiment, perhaps reflecting the soil’s high buffering capacity to changes in pH and indicating that rainfall pH may not be an important factor affecting leaching of heavy metals (data not shown). However, under field conditions rainfall pH may be more important in the long term.

3.6. Amounts of soil macronutrients and heavy metals leached

The amounts of Fe, Ca and Mg leached are shown in Table 4. Loss of Fe increased markedly with increasing EDTA dosage. Calcium and Mg were leached at the

* Data are means of three observations ± S.E.

* Please see Table 1 for details of each treatment number.
When EDTA was added to soil at the rates of 3, 6 or 12 mmol kg\(^{-1}\), the losses were 11.2–15.6, 22.1–23.1 and 37.5–41.1% of total Cu. There was no significant effect of leaching volume or pH on Cu loss. Losses of Zn, Pb and Cd were similar to those of Cu.

Linear regression analysis revealed that Cu, Zn, Pb and Cd losses were closely related to EDTA according to the following equations:

- **Cu loss (mg kg\(^{-1}\))**
  
  \[ 5.17 \times \text{EDTA (mmol kg}^{-1}\) + 6.86 \]
  
  \[ r = 0.97, n = 12, P < 0.001; \]

- **Zn loss (mg kg\(^{-1}\))**
  
  \[ 29.4 \times \text{EDTA (mmol kg}^{-1}\) + 47.2 \]
  
  \[ r = 0.99, n = 12, P < 0.001; \]

- **Pb loss (mg kg\(^{-1}\))**
  
  \[ 26.0 \times \text{EDTA (mmol kg}^{-1}\) + 12.0 \]
  
  \[ r = 0.99, n = 12, P < 0.001; \]

- **Cd loss (mg kg\(^{-1}\))**
  
  \[ 2.96 \times \text{EDTA (mmol kg}^{-1}\) + 4.19 \]
  
  \[ r = 0.98, n = 12, P < 0.001. \]

If the amounts of Cu, Zn, Pb and Cd lost are expressed in mmol kg\(^{-1}\), then the molar ratio of EDTA-to-combined metal losses was 0.68. Thus, about 2/3 of the added EDTA was used to chelate soil Cu, Zn, Pb and Cd and moved out to the 0–20 cm ‘arable’ layer. The remaining 1/3 of added EDTA chelated soil Fe, Ca, Mg and other ions.

During phytoremediation enhancement procedures, EDTA solution is usually applied when adequate plant biomass has accumulated, and plant shoots are often harvested about 1 week later (Blaylock et al., 1997; Huang et al., 1997). When EDTA is applied, soil contaminants are mobilized significantly, and will often be maintained at high concentrations in the soil for a long time. Thus, before EDTA is degraded to a low concentration, by which time its effect on the mobility of soil contaminants will be negligible, the side effects of EDTA enhancement in phytoremediation should give cause for concern. In a lysimeter study, Romkens et al. (2002) added 0.01 M EDTA twice within 1 week and this resulted in high concentrations of Cu and Cd in leachate. In field trials 0.5–2.5 g (1.3–6.7 mmol kg\(^{-1}\) ) of EDTA has been used as a chelate in phytoremediation (Huang et al., 1997; Blaylock et al., 1997; Ebbs and Kochian, 1998). Thus,
0.01 M EDTA was a very high dosage, especially for a sandy soil, this may explain the high concentrations of Cd and Cu found in leachate.

Leaching will occur once the soil is saturated. The soil used in our experiment was a clay-loam with a water holding capacity (WHC) of 47.9%. If soil water content was 60% of WHC, there would still be 40% of WHC required to reach saturation. If we assume that the arable layer is 20 cm deep, then rainfall over 38 mm will saturate the soil (starting at 60% WHC) and then leach the EDTA-mobilized heavy metals to groundwater. Thus, heavy rainfall will produce a high risk of heavy metal. In Tai Lake region in east China, during the heavy rainfall season chelate-assisted phytoremediation would not be an appropriate technique because results from the pot experiment indicate that EDTA application would markedly enhance soil Cu, Zn, Pb and Cd mobility for a period of about 1 month. Where rainfall or irrigation is heavy enough to saturate the soil, and where leaching water cannot be collected, chelate-based phytoremediation behavior should be carefully managed to avoid the risk of heavy metal contamination of groundwater.

3.7. Phytoremediation potential of the soil using EDTA enhancement

EDTA (disodium salt, 3 mmol kg$^{-1}$) added to a heavy paddy soil significantly enhanced the mobility of soil Cu (the historical contaminant) and Pb (one of the newly introduced contaminants but one easily precipitated) but had no effect on Zn and Cd, which were both newly introduced pollutants. Concentrations of Cu and Pb in shoots of Indian mustard were also increased by EDTA addition. Despite the above effects, uptakes of Cu, Zn, Pb and Cd by the plants were only 0.11, 0.44, 0.02 and 0.39%, respectively, of the soil total Cu, Zn, Pb and Cd. To achieve cleanup of this contaminated soil to normal Cu, Zn, Pb and Cd concentrations, a sequence of 753, 205, 6088 or 255 crops of Indian mustard would be required. Thus, chelate-enhanced phytoextraction might not be an adequate technique for this soil, even for Pb or Cu.
