(Received 2 June 2008; revised manuscript received 8 August 2008; published 3 December 2008)

We demonstrate that perfect state transfer can be achieved using an engineered spin chain and clean local end-chain operations, without requiring the initialization of the state of the medium nor fine-tuning of control pulses. This considerably relaxes the prerequisites for obtaining reliable transfer of quantum information across interacting-spin systems. Moreover, it allows us to shed light on the interplay among purity, entanglement, and operations on a class of many-body systems potentially useful for quantum information processing tasks.

DOI: 10.1103/PhysRevLett.101.230502

The ability to prepare a fiducial state of a quantum system that has to accomplish a task of quantum communication or computation is one of seven desiderata, more commonly known as DiVincenzo’s criteria [1], that any reliable device for quantum information processing (QIP) should meet. However, even the innocent request for a pure reference state for the initialization of a QIP device is not easily granted, in practice, mainly due to the difficulty of preparing pure states of multipartite systems. A striking example is given by nuclear-magnetic-resonance QIP [2], where the signal observed in an experiment comes from a chaotic ensemble of emitters, whose overall state is strongly mixed, and is “reinterpreted” quantum mechanically by relying on the concept of pseudopurity [3]. Another very important instance is provided by schemes for quantum state transfer (QST) in spin chains [4]. These have emerged as remarkable candidates for the realization of faithful short-distance transmission of quantum information across interacting-spin systems. Moreover, it allows us to shed light on the interplay among purity, entanglement, and operations on a class of many-body systems potentially useful for quantum information processing tasks.

We demonstrate that perfect state transfer can be achieved using an engineered spin chain and clean local end-chain operations, without requiring the initialization of the state of the medium nor fine-tuning of control pulses. This considerably relaxes the prerequisites for obtaining reliable transfer of quantum information across interacting-spin systems. Moreover, it allows us to shed light on the interplay among purity, entanglement, and operations on a class of many-body systems potentially useful for quantum information processing tasks.

With minimal changes, one can use any Hamiltonian satisfying particular conditions on the time-evolution of two-site operators, as clearly identified in this Letter.

To provide the details of our protocol, we address the cases of two models for QST in spin chains which have been widely used so far [6,9]. We start with a nearest-neighbor Ising coupling involving N spin-1/2 particles that also experience a transverse magnetic field. Its Hamiltonian reads $\hat{H}_1 = \sum_{i=1}^{N-1} J_i \hat{Z}_i \hat{Z}_{i+1} + \sum_{i=1}^{N-1} B_i \hat{X}_i$. Here, $J_i$ is the interaction strength between spin $i$ and $i+1$ and $B_i$ is the strength of the coupling of spin $i$ to a local magnetic field. In our notation, $\hat{X}$, $\hat{Y}$, and $\hat{Z}$ denote the $x$, $y$, and $z$ Pauli matrix, respectively. We choose $J_i = J\sqrt{4i(N-i)}$ and $B_i = J\sqrt{(2i-1)(2N-2i+1)}$ with $J$ being a characteristic energy scale that depends on the specific physical implementation of the model (we choose units such that $\hbar = 1$ throughout the Letter). By applying the single-spin operation $(\hat{I} + i\hat{X})/\sqrt{2}$ on the first element of the chain and using the eigenstates $|\pm\rangle = (|0\rangle \pm |1\rangle)/\sqrt{2}$ of the $\hat{X}$ operator as computational basis, end-to-end perfect QST is achieved via $\hat{H}_1$, when $J t^* = \pi/4 \;(t^* \text{ is the evolution time})$ and for the initial fiducial state $|+,\ldots,\rangle_{2,...,N}$ of the spin medium [6]. This result has been obtained by analyzing the system from an information-flux (IF) viewpoint [10]. However, the state-transfer fidelity is sensitive to deviations of the initial state from the one being ideally required.

For the understanding of the following discussion, it is enough to mention that the IF is in general rather useful when information regarding multisite correlation functions is needed [11]. The analysis is performed in Heisenberg picture and requires $\hat{O}(t)$, i.e., the time-evolved form of a given chain operator $\hat{O}$. Here, for the purposes of our study, we concentrate on the evolution of two-site operators $\hat{I}_{i+1} \hat{X}_{N-i+1}$, $\hat{Z}_i \hat{Y}_{N-i+1}$, and $\hat{Z}_i \hat{Z}_{N-i+1}$. At time $t^* = \pi/4J$, by solving the relevant Heisenberg equations, we have that

$$
\hat{I}(t^*) = \hat{X}_{N-i+1}(t^*) = \hat{X}_{N-i+1},
\hat{Y}_i(t^*) = \hat{Y}_{N-i+1}(t^*) = \hat{Y}_{N-i+1},
\hat{Z}_i(t^*) = \hat{Z}_{N-i+1}(t^*) = \hat{Z}_{N-i+1}.
$$

\[1\]
Clearly, each of these two-site operators evolves in its swapped version, without any dependence on other chain’s operators. This paves the way to the core of our protocol, which we now describe qualitatively. Qubit 1 is initialized in the input state $\rho^i$ (either a pure or mixed state) we want to transfer and qubit $N$ is projected onto an eigenstate of $\hat{Z}$. Then the interaction encompassed by $\hat{H}_1$ is switched on for a time $t' = \pi/4J$, after which we end up with an entangled state of the chain. The amount of entanglement shared by the elements of the chain depends critically on their initial state, as it is commented later on. Regardless of the amount of entanglement being set, a $\hat{Z}$ measurement over the first spin projects the fraction of genuine Horne-Zeilinger (GHZ) form $[12]$ is shared by the elements of the chain. Such fraction is maximum for $i$-th spin if $\rho^i$ in the input state $(X\rho^i X)$. In any case, apart from a simple single-spin transformation, perfect state transfer is achieved. For completeness of presentation, here we quantitatively assess the performance of our proposal.

We start by considering spins $2, \ldots, N - 1$ all prepared in (unknown) eigenstates of the $\hat{Z}$ operator. For simplicity, we assume a pure state $|\psi\rangle = \alpha |0\rangle + \beta |1\rangle$ to be transmitted and the last spin in $|0\rangle$, although the generalization is straightforward. For definiteness, a representative of the initial state of the medium is written as $|a_2 \ldots a_{N-1}\rangle_2 \ldots \_N$ with $|a_i\rangle_i$ the state of spin $i$ ($a_i = 0, 1$). The final state of the chain, $e^{-i\hat{H}_1 t'} |\psi\rangle_i |a_2 \ldots a_{N-1}\rangle_2 \ldots \_N$, is found to be $|\Psi_T\rangle = (1/\sqrt{2})[|0\rangle_i |a_N \ldots a_2\rangle_2 \ldots \_N|\psi\rangle_N + i|1\rangle_i |a_N \ldots a_2\rangle_2 \ldots \_N(X|\psi\rangle_N)]$, where $\langle a_i^+ | a_i \rangle = 0, \forall i$. Thus, upon measurement of the first spin over the $\hat{Z}$ eigenbasis, the state of the last spin is clearly locally equivalent to $|\psi\rangle$ (and separable with respect to the sub-system $\{2, \ldots, N - 1\}$). The form of $|\Psi_T\rangle$ reveals the core of our mechanism. In fact, before the measurement core, a fraction of genuine $N$-party entanglement of Greenberger-Horne-Zeilinger (GHZ) form $[12]$ is shared by the elements of the chain. Such state is optimal for transferring a pure state $|\phi\rangle_N = (\sqrt{p_{00}} |0\rangle_N + e^{i\theta} \sqrt{1 - p_{00}} |1\rangle_N)$ with the state of the last qubit after the protocol), which is unity when the two states are the same and zero when they are mutually orthogonal. We have that $F_{\text{transfer}} = p_{00} + (1 - p_{00}) \text{Tr}(|\psi\rangle \langle \psi| X)$, where $p_{00} \in [0, 1]$ is the population of $|0\rangle$ in the density matrix describing the initial state of spin $N$ (decomposed over the $\hat{Z}$ basis). The independence of the state fidelity from the coherences of the initial state of $N$ implies that it is effectively the same to operate with a pure state $|\phi\rangle_N = (\sqrt{p_{00}} |0\rangle_N + e^{i\theta} \sqrt{1 - p_{00}} |1\rangle_N)$ with $\gamma$ arbitrary. Any error in the QST process has to be ascribed to the fact that, for a nonunit value of $p_{00}$, the perfectly transmitted state $|\phi\rangle$ has an admixture with the “wrong” state $X|\psi\rangle$. This explains the dependence of $F_{\text{transfer}}$ on the state to be transmitted (more precisely, on $\langle \phi | X | \psi \rangle$).

As anticipated, our results are not bound to the specific instance of interaction model being considered but, more generally, on the way two-site operators evolve in time. Under different couplings, similar behaviors for objects like $\hat{O}(t')\hat{O}_{N-i+1}(t')$ can be observed, therefore leading to conclusions similar to those put forward in our discussion so far. In fact, with rather minor adjustments to the procedure described above, one can apply the scheme to any spin-$1/2$ particles coupled via the $XX$ model $\hat{H}_2 = \sum_{i=1}^{N-1} K_i (\hat{X}_i \hat{X}_{i+1} + \hat{Y}_i \hat{Y}_{i+1})$ with $K_i = J \sqrt{\cos i \sqrt{(N - i)}}$. $\hat{H}_2$
has been extensively analyzed [9]: \(1 \rightarrow N\) perfect QST is achieved when the initial state of all the spins but the first one is \(|0\rangle\). However, let us reason in terms of IF again, proceed as done above for the Ising model and look at the dynamics of two-site operators symmetrical with respect to the center of the chain. At time \(t^* = \pi/4J\), we have that, for any \(N\), \(\hat{X}(t^*)\hat{Z}_{N-i+1}(t^*) = \hat{Z}_i\hat{X}_{N-i+1}\). On the other hand, for even \(N\) we find

\[
\hat{X}_i(t^*)\hat{X}_{N-i+1}(t^*) = \hat{X}_i\hat{X}_{N-i+1},
\]

(2)

while for an odd number of spins in the chain we have

\[
\hat{X}_i(t^*)\hat{X}_{N-i+1}(t^*) = \hat{Y}_i\hat{X}_{N-i+1},
\]

(3)

The procedure to follow has to be adjusted depending on the chain’s length. In particular, the last spin has to be projected onto \(|\pm_N\rangle = (|0\rangle \pm e^{i\pi/2}|1\rangle)/\sqrt{2}\). In what follows, we say that outcome \(+1\) (\(-1\)) is found if a projection onto \(|+N\rangle\) (\(-|N\rangle\)) is performed. This change of basis with respect to the protocol designed for the Ising model is due to the different form of the transverse nature of \(\hat{H}_2\). After the evolution \(e^{-i\hat{H}_2t^*}\), we measure the first spin over the \(\hat{X}\) eigenbasis. The resulting output state depends on the product of the measurement outcomes at \(1\) (after the evolution) and \(N\) (before the evolution). If such product is \(+1\) (\(-1\)), the transmitted state will be \((\hat{T}\hat{N})^1\hat{\rho}^{in}(\hat{T}\hat{N})^1|\hat{T}\hat{N}\rangle\langle\hat{T}\hat{N}|\), where \(\hat{T} = |0\rangle\langle0| + e^{i\pi/2}|1\rangle\langle1|\) (therefore, \(\hat{T}^2 = \hat{Z}\)). Also in this case, apart from a single-spin transformation, perfect state transfer is achieved. A sketch of the general scheme for perfect state transfer is presented in Fig. 1. For the XX model, we can write the final state of the system before the \(M_2\)-measurement stage (we consider the last spin in \(|+N\rangle\)), as \(\rho_F = (|+\rangle + |\rangle\langle+|_N) \otimes \hat{\rho}_{XX} \otimes |+\rangle_{N-1} \otimes \langle+|_{N-1}|\langle+|_{N-1}|\otimes -\rangle_{N-1} \times (-1) \hat{S}_{3}\hat{\rho} \otimes \hat{T}_{3}\hat{\rho}_{N} \otimes |i(1-1N)|_{N} + (-1) \hat{S}_{3}\hat{\rho} \otimes \hat{T}_{3}\hat{\rho}_{N} + \text{H.c.})/2\), with \(\hat{T} = \hat{A}\hat{A}\), \(\hat{\rho}_{XX} = (\hat{T}\hat{N})^1\hat{\rho}^{in}(\hat{T}\hat{N})^1\), \(\hat{A} = \prod_{i=1}^{N-1}\hat{T}_{i}, \hat{S}_{3}\hat{\rho} = \hat{\rho}_{XX} \hat{Z}_{N}, \hat{S}_{4}\hat{\rho} = \prod_{i=1}^{N-1}\hat{Z}_{i}\hat{\rho} \prod_{i=1}^{N-1}\hat{Z}_{i}, \hat{T}_{3}\hat{\rho}_{N} = \hat{\rho}_{XX}\hat{Z}_{N}, \hat{T}_{4}\hat{\rho}_{N} = \hat{Z}_{N}\hat{\rho}_{XX}\hat{Z}_{N}\).

In general, the protocol can be adapted to any Hamiltonian for which we can find a triplet of single-spin operators \(\hat{B}, \hat{C}, \hat{D}\) such that, for symmetric spin pairs, we have \(\hat{B}_i(\hat{T}_i)\hat{C}_{N-i+1}\hat{D}_{N-i+1}(\hat{T}_i) = O_i\hat{D}_{N-i+1}\). Here, \(\hat{B}_i(\hat{D}_{N-i+1})\) provides the eigenbasis for the measurement over spin \(i\) \((N-i+1)\) of the chain after (before) the evolution, \(\hat{C}_{N-i+1}\) is a decoding operation, \(\hat{O}_i = \hat{D}_i(0) = X, Y, Z\) and \(j_0, k_0, l_0 = 0, 1\), depending on the coupling model. For instance, Eqs. (1) are gained by taking \(\hat{B}_i = \hat{Z}_i, \hat{C}_{N-i+1} = 1, \hat{D}_{N-i+1} = \hat{Z}_{N-i+1}\) with \(j_0 = k_0 = 0, j_0, k_0, l_0 = 1\). We point out that when these conditions are not fulfilled, as in Ref. [13] where an antiferromagnetic Heisenberg chain is used, our protocol can still be rather successful. In these cases, through IF we can calculate an estimate of the average transfer fidelity [10]. For instance, for a homogeneous XX model of \(N = 100\) spins with endpoint coupling strengths \(J_1 = J_{N-1} = 0.7J\), the average transfer fidelity via our protocol is estimated to be \(\geq 0.87\).

As noticed for the case of \(\hat{H}_1\), the nature and amount of the entanglement generated during the performance of the protocol depends on the form of the initial state of the medium’s spins. Multiparticle entanglement shared by all (or some of) the elements of the chain, as well as only bipartite entanglement involving first and last qubits (as in the case when spins from \(2\) to \(N - 1\) are in eigenstates of \(\hat{X}\) can be generated. Nevertheless, unit fidelity of transfer is achieved when the right time evolution and perfect hard projections are in order. This strongly supports the idea that QST protocols do not crucially rely on the specific nature and quality of the entanglement generated throughout the many-body dynamics, in stark contrast with other schemes for QIP [14].

On the other hand, the counterintuitive fact that \(F_{\text{transfer}} = 1\) regardless the initial state of medium could remind one, at first sight, of the idea of deterministic quantum computation with one quantum bit (DQC1) proposed in Ref. [15]. In this model, a single pure two-level system and arbitrarily many ancillae prepared in a maximally mixed state are used in order to solve problems for which no efficient classical algorithm is known. The apparent similarity with our case is resolved by observing that in DQC1 the initial state is restricted to that particular instance (a pure single-qubit state and a maximally mixed state of all the other qubits), which can be seen as the “fiducial” state invoked in DiVincenzo’s criterion. Differently, our scheme completely relaxes the knowledge required about the state of the spin-medium, which might be completely unknown to the agents that perform the QST process. The achievement of quantum computation with initial mixed states has also been analyzed in Ref. [16], where it has been shown that a single qubit supported by a collection of qubits in an arbitrary mixed state is sufficient to efficiently implement Shor’s factorization algorithm. In this case, however, the performance of the protocol depends on the input state. Indeed, the average efficiency over all the possible random states (mixed or pure) is evaluated, but for some particular input states (for instance, \(|0...0\rangle^N\)) it can drop below classical limit. Differently, our scheme is independent of the initialization of the spin-
medium and its efficiency cannot be spoiled by any input state.

It is worth clarifying an important aspect which is certainly apparent to the careful reader. The procedures described so far might remind one of the general scheme for one-way computation put forward in Ref. [17]. In both cases, the optimal result of a protocol depends on the performance of perfect projective measurements onto specific elements of a register and the feed-forward of a certain amount of classical information (in our case, the outcome of the measurements over spin 1 and/or the initial projection of spin N). Moreover, as in the one-way model, in our proposal the “pattern” of quantum correlations depends on the initial state of the elements of the system. However, such an analogy cannot be pushed too far as, remarkably, the use of quantum entanglement in the two protocols is rather different. While the one-way model relies on a prebuilt multipartite entangled resource (the graph state) which is progressively destroyed by a proper program of measurements, in our scheme the multipartite entanglement (if any) is built while the protocol is running.

We just need a single measurement for the processing of the information encoded at the input state. In addition, differently from a graph state, the preparation of some of the spins in the medium in states preventing their participation to a multipartite entangled state does not spoil the efficiency of the protocol, as we have demonstrated. This is not the case for a graph-state built out of pairwise Ising interactions: the wrong initialization of a part of the register excludes it from the overall entangled state, and actually “blocks” the transfer of information through that region of the register.

Finally, we would like to stress the difference between our approach and those achieving perfect QST via mirror-inverting coupling model [18]. In our general protocol, mirror inversion is “induced” in models in which otherwise would not allow it, by adjusting the pattern of quantum interferences within the spin medium via the encoding or decoding local stages. By means of these, one can avoid the preengineered fulfillment of precise conditions on the spectrum of each interacting spin [18,19] which, combined with reflection symmetry, are required for mirror inversion. Our models satisfy just the second of these conditions, perfect QST without initialization being achieved through the encoding and decoding steps we have described.

We have shown the existence of a simple control-limited scheme for the achievement of perfect QST in a system of interacting spins without the necessity of demanding state initialization. Our flexible protocol requires just one-shot unitary evolution and end-chain local operations. Its efficiency arises from the establishment of correlations between the first and last spin of the transmission chain. With the exception of limiting cases where the transfer is automatically achieved [as for the transfer of eigenstates of  \( \hat{X}_1 \) (\( \hat{Z}_1 \)) when model \( \hat{H}_1 \) (\( \hat{H}_2 \)) is used], these are set regardless of the state of the spin medium, their amount being a case-dependent issue. The end-chain measurements, which are key to our scheme, “adjust” such correlations in a way so as to achieve perfect QST. We hope that our study, which paves the way to a thorough investigation about the role played by multipartite entanglement in perfect QST, would help in the experimental realization of short-distance quantum communication in, for instance, engineered superconducting chains or patterned distributed nanosystems.
