Abstract

Virtual topology operations have been utilized to generate an analysis topology definition suitable for downstream mesh generation. Detailed descriptions are provided for virtual topology merge and split operations for all topological entities. Current virtual topology technology is extended to allow the virtual partitioning of volume cells and the topological queries required to carry out each operation are provided. Virtual representations are robustly linked to the underlying geometric definition through an analysis topology. The analysis topology and all associated virtual and topological dependencies are automatically updated after each virtual operation, providing the link to the underlying CAD geometry. Therefore, a valid description of the analysis topology, including relative orientations, is maintained. This enables downstream operations, such as the merging or partitioning of virtual entities, and interrogations, such as determining if a specific meshing strategy can be applied to the virtual volume cells, to be performed on the analysis topology description. As the virtual representation is a non-manifold description of the sub-divided domain the interfaces between cells are recorded automatically. This enables the advantages of non-manifold modelling to be exploited within the manifold modelling environment of a major commercial CAD system, without any adaptation of the underlying CAD model. A hierarchical virtual structure is maintained where virtual entities are merged or partitioned. This has a major benefit over existing solutions as the virtual dependencies are stored in an open and accessible manner, providing the analyst with the freedom to create, modify and edit the analysis topology in any preferred sequence, whilst the original CAD geometry is not disturbed. Robust definitions of the topological and virtual dependencies enable the same virtual topology definitions to be accessed, interrogated and manipulated within multiple different CAD packages and linked to the underlying geometry.

Keywords: Virtual Topology; clean-up; decomposition; hex meshing schemes;

1. Introduction

Geometry preparation and manipulation for meshing is an important aspect of finite element analysis (FEA) processes, but can often consume an overwhelming proportion of the overall analysis cycle [1]. The geometry handling cost heavily depends on the analysis being performed, the toolsets being used and the expertise of the analyst. For example, any of tetrahedral (Tet), hexahedral (Hex), mixed-solid element, dimensionally-reduced or mixed-dimensional meshes may be appropriate depending on the type of analysis being performed. The meshing style in turn dictates the level of geometry manipulation necessary to achieve a fit-for-purpose mesh. Suitable Tet meshes are frequently generated using only geometry clean-up operations to remove features that may hinder the mesh generator, or are very small compared to the target element size. In contrast, due to the lack of robust automated Hex mesh generation technology, it is often necessary to utilize decomposition techniques in addition to geometry clean-up in order to successfully create a Hex mesh. Decomposition methods partition complex domains into simpler sub-domains which can be readily Hex meshed using algorithms such as mapping, sub-mapping, mid-point subdivision and sweeping.

The time spent executing the preferred clean-up and decomposition operations is influenced by the toolsets selected for each task. A plethora of geometry-based tools exist for directly modifying the geometry of domain. These tools tend to be time intensive to use and can produce discrepancies in the model. An example is the use of sew or join operations to merge faces for geometry clean-up, where there is no guarantee a surface definition for the combined entities can be generated. Furthermore, these geometry-based CAD approaches require analysts to have significant CAD modelling experience, which imposes a significant and unnecessary burden on the analyst, and the geometry cleanup operations must be repeated for any new design iteration. Direct geometry modifications, their overheads, and the sometimes unpredictable results can be avoided using virtual topology operations [2] for model editing. The principal role of virtual topology is to modify the topology whilst leaving the geometry undisturbed. Other notable advantages include the ease of reversing virtual topology operations in comparison to geometry-based operations and the analyst-friendly nature of virtual topology toolsets. Virtual topology is one of the underlying technologies used when defining Simulation Intent [3]. Defining Simulation Intent involves capturing high level modelling and idealization decisions in order to create an efficient and fit-
for-purpose analysis. For example, if an analyst specifies the desired solution accuracy and time available then automated decisions can be made which dictate analysis attributes, such as mesh type or target element size, in order to achieve the desired results. Furthermore, the target element size dictates the input metric for virtual topology clean-up operations based on entity size.

Whilst virtual topology is commonly used for geometry clean-up, it has yet to be entirely embraced for volume decomposition for meshing where complex domains can be Hex meshed using a divide-and-conquer approach to generate mesh-able primitives. This work describes a virtual topology implementation that has been used with a commercial CAD package and linked to the underlying CAD geometry. Virtual decomposition is implemented for an industrial use-case model based upon the input from a thin-sheet identification tool. The generation of an analysis topology using virtual topology operations enables tools to operate in the presence of virtual topology including the identification of appropriate meshing strategies for subset cells. Once virtual merge or split operations have been defined all topological relationships are automatically managed.

2. State-of-the art virtual topology implementations

Virtual topology is not new [2,4], but through using a number of state-of-the-art geometry pre-processing and meshing packages (including Abaqus CAE [5], Ansys Workbench [6], CUBIT [7], ICEM CFD [8] and Siemens NX [9]) it is apparent that its advantages are not yet readily available in all of them. Also, there is no agreed description for virtual topology which can be exported between packages.

The aforementioned packages predominantly recognize virtual topology as a geometry clean-up tool for mesh generation. Typically a series of virtual topology operations are available to merge small edges/faces below the target element size, collapse small angles that would compromise mesh quality, or to partition entities to constrain the mesh direction and/or size for boundary condition application. The availability of virtual topology capabilities varies between the different CAE packages, as does the level to which they can be accessed through the user interface and API.

One drawback to current implementations is that many packages do not allow virtual topology to be viewed, interrogated or edited once it has been applied. Restricting the analyst from viewing the virtual topology that has been defined is a major hindrance within analysis workflows, especially for complex models where numerous virtual operations are utilized or different toolsets are being used. This leaves it extremely challenging for different analysts to share models and interpret the abstraction decisions of others. This is a concern within large companies where multiple analysts may be required to operate on the same analysis models. The lack of accessibility means the analyst is restricted from using favored toolsets within different aspects of the analysis process. It has been demonstrated in earlier work [10] that the ability to extract and store virtual topology relationships enables its reuse within other packages. Such benefits require complete access to virtual operations to enable analysis model compatibility in different packages.

Some vendors have elected to implement virtual topology on a polygonal representation of the design model. This simplifies the automatic detection and definition of virtual topology operations but relies on a robust relationship between geometric and polygonal representations. This can compromise the ability to preserve virtual topology after even simple design changes. A simple yet powerful illustration of this is shown in Fig. 1 (a) for a geometric model generated within Siemens NX. Virtual merge operations are used to remove the edges highlighted in Fig. 1 (a) and create the simplified virtual model in Fig. 1 (b). Once the geometric representation is edited and the chamfer size increased, Fig. 1 (c), the previously applied virtual operations are no longer in the model, Fig. 1 (d).

Fig. 1 (a) base geometric model; (b) virtual polygonal representation; (c) chamfer size increased; (d) virtual topology operations lost.

One common theme amongst all of the aforementioned meshing packages is the lack of robust virtual splitting operations for volume cells. Virtual volume partitioning could be used, for example, to allow an analyst to virtually decompose a domain for Hex meshing. Splitting operations do exist to partition edges and faces and
have been utilized to decompose domains and generate a virtual topology network of multi-block faces for quad
decompose an initial volume into sub-volumes mesh-able by means of basic meshing methods. The virtual
volume decomposition implemented within the GAMBIT meshing suite [13] imposes the constraint that all
dges of the partitioning faces are required to be connected to the volume to be partitioned resulting in multiple
connected partitioning faces which need to be merged. In other work by Sheffer [14] virtual volume
decomposition was introduced but lacked a detailed description of its implementation. CUBIT offers a virtual
volume partitioning solution at the mesh level, where a meshed domain can be partitioned by specifying
distance criteria to select elements and define the partitioning location. In similar work, a volume sub-mapping
approach utilizes a virtual decomposition to pre-process the geometry for hex meshing, but requires that all
boundary surfaces have been meshed with a quadrilateral mapping algorithm [15]. ICEM CFD [8] provides a
block decomposition solution by manually creating and overlaying a network of simple block topologies on top
of the geometry. The block topology can be thought of as a virtual representation of the geometry but without
having to carry out the decomposition as links to the geometry tend to be manually specified in order to capture
the underlying shape of the domain. This is in contrast to the approach herein, where partitioning entities are
used to generate a virtual representation with all links to the underlying geometry automatically retained. Virtual
merge operations tend to be implicit whereby multiple block faces can be linked to a single geometric face or a
single block face can represent multiple geometric faces.

Apart from the virtual decomposition contributions mentioned above most packages and research tend to
primarily use direct geometric operations to decompose volume cells [16]. Successful partitioning of the
generic representation can be troublesome, especially where non-manifold conditions (shared faces, dangling
dges etc.) are generated within manifold environments. Even if the domain has been successfully decomposed
it is common for unwanted geometric and topological entities, such as sliver faces, to be generated which
require further work to remove. The use of direct geometric partitioning, alongside a virtual description defined
on a polygonal representation, demands that partitioning operations need to be carried out prior to any virtual
operations. This can be detrimental, especially if the virtual topology fails to update as the design model
evolves. In this work it is shown that it is possible to execute virtual merge or split operations in any order
desired by the analyst. This is achieved by storing the virtual topology dependencies alongside a description of
the analysis topology. It is described herein how virtual merge and split procedures, including volume
decomposition, are implemented and how the relationship between the virtual entities and the analysis topology
is stored. Formulation of an analysis topology enables multiple versions of the original topology to be generated
for different analyses, interrogated and manipulated as deemed necessary by an analyst.

3. Defining virtual topology operations

This section describes the implementation of virtual merge and split operations and the generation of an
appropriate analysis topology, where entities (real or virtual) can be merged or partitioned. A valid topological
description, including the relative orientations of entities, is maintained within the analysis topology definition.
This helps downstream virtual operations and enables the analysis topology to be interrogated for meshing
purposes. The topological description is managed automatically once the virtual operations are defined. Entity
labels are assigned within a generic relational database [17] to guarantee unique identifiers, but have been
labelled here based on entity type (f for face, e for edge and v for vertex) for clarity. Descriptions of the
topological queries required to generate the analysis topology are provided throughout this section.

3.1. Virtual merge operations

Virtual merge operations create a single virtual superset entity by removing the common lower dimension
boundary between adjacent entities being merged. The entities being merged, referred to as host entities, must
be adjacent and have the same manifold dimension, which the virtual superset entity inherits from its hosts.

Fig. 2 illustrates the merge operation for edge entities. Adjacent edges ‘e1’ and ‘e2’ are shown in Fig. 2 (a)
along with their bounding vertices and the orientation of each vertex relative to its bounded edge. The oriented
virtual edge (e3, +1) is formed by merging (e1, +1) and (e2, -1). If the underlying edge tangent points towards a
vertex then it is assigned a positive orientation relative to the edge, otherwise it is negative, Fig. 2 (a). The
bounding topology of the virtual superset edge, ‘e3’, is established by finding the uncommon boundary, vertices
‘v1’ and ‘v3’, between the host edges being merged, Fig. 2 (b). Consistent orientations of the bounding vertices
are maintained by selecting the orientation of the first ‘uncommon’ vertex, ‘v1’, and assigning the second
vertex, ‘v3’, in the opposite direction. The orientation of the superset edge relative to any bounded faces is set to
be the same as the host edge bounded by the first uncommon vertex. The virtual dependencies between the
virtual and host edges are recorded, Fig. 2 (c), and the topological boundaries updated in the analysis topology definition.

Fig. 2 (a) Host edges to be merged; (b) virtual superset edge; (c) virtual and topological dependencies.

Fig. 3 (a) Host faces to be merged; (b) resulting analysis topology; (c) ignored edge face pair – e10; (d) ignored edge face pair – e16; (e) ignored edge face pair – e17; (f) virtual dependencies of face cells.

It is possible to define virtual superset faces by specifying the faces to be merged or the edges to be ignored (i.e. the common edges between faces to be merged). Either approach is sufficient when creating virtual superset faces one-by-one. However, this is not the case when attempting to create many at once, which is useful when attempting to automate geometry clean-up procedures. Consider Fig. 3 where the objective is to generate two superset faces ‘f7’ and ‘f8’, Fig. 3 (b), by merging faces ‘f2’, ‘f3’, ‘f4’, ‘f5’ and ‘f6’, Fig. 3 (a). Simply providing the faces to be merged as the input leaves it impossible to interpret the intent of the analyst and generate the two superset faces, ‘f7’ and ‘f8’. Instead an attempt will be made to create one face, as all share a common edge. However, if the input provided is the edges to be ignored, ‘e10’, ‘e16’, ‘e17’ and ‘e20’, then by finding the bounded faces of each edge, {f2, f3}, {f4, f5}, {f5, f6} and {f5, f6} respectively, shown in Fig. 3 (c), (d) and (e), the supersets are formed by recursively cycling through each face pair, and merging them. This also enforces the condition that faces to be merged must be adjacent. From this it can be seen that superset faces ‘f7’ and ‘f8’, comprised of host faces {f2, f3} and {f4, f5, f6} respectively, are identified. The virtual dependencies for the superset faces are shown in Fig. 3 (f). Note that all the component faces in the new superset face retain
their original relative orientation to the underlying geometry, which may mean they have different orientations relative to the virtual face created.

In order to create the topology of the superset faces, associated bounding entity topologies must also be merged. Since the edges to be ignored are used as the input, their bounding vertices may also be ignored. The bounded edge pairs are returned for each vertex to be ignored and grouped into host edge sets as per the description for the face pairs above. Once the host edge sets are identified the merge operation for edges is used to create the superset edges. It should be noted that certain vertices are not ignored if they bound an edge which does not form the boundary of the superset face or is not ignored as part of another merge operation, e.g. the vertex bounding edge ‘e16’ bounds more than two edges (it is common to edges ‘e9’, ‘e5’ and ‘e6’). It is important that this is not ignored as edge ‘e9’ bounds face ‘f1’ and thus remains in the resulting analysis topology, Fig. 3 (b). Edge loop types are liable to be altered within the analysis topology. For example, edges ‘e18’ and ‘e19’ are classed as outer loop edges of faces ‘f5’ and ‘f6’. However, after host faces ‘f5’ and ‘f6’ are merged the common edges ‘e17’ and ‘e20’ are removed from the analysis topology and superset edge ‘e24’ becomes an inner loop periodic edge as it originally existed as two edges ‘e18’ and ‘19’ are merged through the removal of ‘e17’ and ‘e20’ and their bounding vertices. These situations are recognized when there are multiple unconnected common edges between the host faces that were merged, e.g. edges ‘e17’ and ‘e20’ from Fig. 3 (a).

An edge is considered positive relative to its bounded face if the face is on the left-hand-side of the forward pointing edge tangent direction when viewed from the outward pointing face normal. For example, edges ‘e1’, ‘e4’, ‘e5’ and ‘e9’ are all positive relative to face ‘f1’. However, edge ‘e5’ is negative relative to its other bounded face ‘f4’. This orientation convention is transferred to maintain a valid topological description within the analysis topology, Fig. 3 (b). Volume cells can also be merged together using the same methodologies described above with any orientation attributes distributed to merged faces.

3.2. Virtual split operations

Virtual subset entities represent a partial section of a host entity. Parasite entities are the virtual bounding entities used to partition a higher dimensional topological entity into virtual subset entities, e.g. a parasite face used to partition a volume cell into simpler subset volumes for meshing. The virtual representation enables parasite entity descriptions to be provided in different formats as preferred, such as isolated geometries (points, curves or bounded surfaces), parameter values (parametric position on a curve, parameter pair representing the bounded section of a curve) or the bounding entities of the parasite (bounding curves of a parasite face).

Fig. 4 Edge splitting operations: (a) Host edge to be split; (b) resulting analysis topology; (c) virtual subset dependencies; (d) periodic edge to be partitioned; (e) parasite vertex introduced to periodic edge; (f) periodic edge partitioned with second parasite vertex.

Split operations are described for all possible edge configurations. The first configuration is an edge bounded by two vertices, Fig. 4 (a). In this scenario the addition of parasite vertex ‘v3’ to the boundary of host edge e1 results in two subset edges ‘e2’ and ‘e3’. The orientation of the parasite ‘v3’ is assigned opposite to the original vertices bounding each virtual edge, e.g. where subset edge ‘e2’ is bounded by negative vertex ‘v1’ this dictates that parasite ‘v3’ is positive relative to subset ‘e2’.
The second configuration is a periodic edge bounded by zero vertices, Fig. 4 (d). Here the addition of a single parasite vertex ‘v1’ is insufficient to partition the host edge ‘e1’, into two subsets, as the boundary traversal arrives back at the initial vertex ‘v1’, Fig. 4 (e). The parasite vertex is simply added to the topology of the edge and assigned both a positive and negative orientation. If another operation in the analysis model preparation requires a second parasite vertex to be added to the edge topology then two subset edges result, Fig. 4 (f). The orientation of the parasite vertices relative to the subset edge is determined by their parametric value within the host edge. Periodic edge configurations are extensible to periodic surfaces, such as cylinders. This approach is able to robustly handle any configuration of periodic edges and faces within the virtual representation. Links to any topological CAD architecture are easily maintained as bounding entities are often introduced to periodic entities to simplify the tracking of the topological connectivity. Here a periodic edge or face can be bounded by zero, one, two or n entities and can also be created for analysis purposes (‘e24’ Fig. 3 (b)) to reduce the propagation of splits through the analysis model.

![Image of face splitting operations](image)

**Fig. 5 Face splitting operations:** (a) Host face to be split; (b) resulting analysis topology; (c) host face to be split; (d) parasite edge connected to an inner edge; (e) second parasite edge to partition the host face, (f) virtual and topological dependencies for (a) and (b).

Face partitioning is carried out by introducing a lower dimensional parasite edge into the host face topology. Due to the possible presence of multiple edge loops a wider range of configurations need to be considered for face partitioning. Fig. 5 (a) and (b) describe a situation where a single parasite edge is sufficient to partition the face. Firstly the bounding vertices of the parasite edge are used to partition the bounding edges of the host face, e.g. ‘v5’ and ‘v6’ partition host edges ‘e2’ and ‘e4’ into virtual subset edges {e6, e7} and {e8, e9} respectively. Then a face traversal procedure is utilized to determine whether a parasite edge partitions the host face. The traversal process begins from the first bounding vertex ‘v5’ of the parasite edge ‘e10’. From this vertex the host face topology is traversed in the positive direction until either the input vertex ‘v5’ or the second bounding vertex ‘v6’ of the parasite edge is met. If the start vertex is met then the face has not been partitioned whereas if the second vertex is met then the face has been partitioned. The edges traversed, edges ‘e6’, ‘e1’ and ‘e8’ form the boundary of the first virtual subset face along with the final traversal over the parasite boundary, which in this case is simply the parasite edge itself. The orientation of the parasite edge is inherited from the previous subset edge in the traversal direction. This is decided by identifying the common vertex and comparing its orientation relative to each edge. If the vertex has the same orientation relative to each edge then the parasite edge is assigned an opposite orientation to the subset edge. If the vertex orientations differ between edges then the parasite edge inherits the orientation of the subset edge. Therefore, edge ‘e10’ is assigned positive relative to subset face ‘f2’ and negative relative to subset ‘f3’. The boundary of the second subset face is defined from the remaining edges bounding the host face, excluding inner loop edges. Inner loop edges, such as ‘e5’, are assigned to the boundary of a virtual subset face by determining if the inner edge lies within the outer boundary parameters space of each subset. This returns the boundary of two subset faces ‘f2’ and ‘f3’ to be {e6, e1, e8, e10} and {e7, e3, e9, e10, e5} respectively as shown in the virtual and topological dependency graph Fig. 5 (f).

Another applicable configuration for face partitioning is shown in Fig. 5 (c-e). In this configuration the subset faces are created by partitioning a host face from its inner loop edge to its outer boundary. The use of a single
parasite edge ‘e8’, Fig. 5 (d), does not partition the host face as the face traversal procedure returns to start vertex v1. After introducing a second parasite edge ‘e9’ the face outer boundary is now partitioned as the traversal process ends at vertex ‘v2’. The final step to confirm the partition is to traverse the parasite boundary. The traversal process continues over the inner loop in the positive direction defining a parasite loop of {e9, e12, e8}. This traversal process is possible by maintaining the correct orientations when partitioning the edges with the parasite vertices and is also used to assign the correct orientation to the parasite edges. This returns the boundary of two subset faces ‘f2’ and ‘f3’ to be {e6, e1, e10, e9, e12, e8} and {e7, e3, e11, e9, e13, e8} respectively, Fig. 5 (e). The nature of the traversal procedure enables multiple parasite edges to be used to partition a face. These parasite edges can be added to the face topology in any order with the process able to correctly determine if the host face has been partitioned.

Periodic edges can also be used to partition faces. One virtual subset face will be bounded by the original host outer boundary and the periodic parasite edge, which will be classed as an inner loop edge. The periodic parasite edge will form the outer boundary of the second virtual subset face.

The process to virtually partition a volume cell is shown in Fig. 6 and illustrated using the simple example in Fig. 7, where a face is used as the parasite entity to partition the volume cell. The parasite face can either be a real geometric face, or a virtual face defined by its bounding entities. With either approach the initial step is to use the lower dimensional bounding edges and vertices, highlighted black in Fig. 7 (b), to partition the applicable faces and edges respectively. Once this is achieved, the objective is to determine if the volume cell has been partitioned. The orientation of the bounding edges of a parasite face is established using the orientations of their host. Doing this for the first bounding parasite edge enables the remaining edges to be traversed and assigned the correct orientation. Using topological traversals to assign and maintain orientations enables even complex networks of parasite entities to inherit consistent orientations from their host entity.

Determining if the volume has been partitioned requires a face traversal process similar to the edge traversal process utilized when partitioning face entities. Here the bounding edges of the parasite faces are traversed in order to determine a face loop on either side of the parasite boundary, Fig. 7 (c). At the first bounding parasite edge both bounded faces are identified, excluding the parasite face itself. Each bounded face is the first face in a distinct parasite face loop. The remaining parasite edges are traversed in the correct order to identify additional loop faces. Loop faces share a common edge with an existing loop face, excluding the bounding parasite edges. The two adjacent face loops identified are shown in Fig. 7 (c). Determining the two adjacent face loops either side of the parasite boundary enables a fast-marching propagation method to help identify if a subset volume has been generated since each adjacent face loop should bound a separate subset volume cell. One adjacent face

![Fig. 6 Virtual volume partitioning process.](image-url)
loop is selected to determine if the volume cell has been partitioned. Using this face loop an edge-face propagation approach is utilized to traverse the faces in the volume. To begin this process the bounding edges (excluding the edges bounding the parasite face) of all faces in the face loop are identified. The edge-face traversal method detects any faces, highlighted black in Fig. 7 (d), that are bounded by these edges. These faces are added to the face loop and the process is repeated with the new set of bounding face loop edges returning the faces highlighted black in Fig. 7 (e), which are appended to the face loop. This process continues until there are no remaining faces to traverse (loop depicted in Fig. 6). Care is taken to ensure only the desired traversals are carried out by excluding edges bounding parasite face and certain non-manifold edges from the traversal process.

If the final face loop does not contain any common faces with the second parasite face loop then the volume has been successfully partitioned with the face loop and the parasite face defining its boundary. The subset volume cells are shown in Fig. 7 (f) and (g) where the second subset volume boundary is defined as the residual faces in the host volume. Parasite face orientations are inherited from the bounding parasite edge orientations where the virtual face normal is specified as the normal between the oriented edges.

The virtual decomposition process was described using a single parasite face to partition the volume cell. It is often the case that multiple parasite faces are required to create a subset volume. Fig. 8 shows a decomposition process using multiple parasite faces. The virtual and topological relationships for the volume and face entities are depicted in Fig. 8 (c). For clarity the edge’s virtual and topological relationships are not shown but are automatically processed in the same manner.

Attempting to partition the host volume ‘b1’, Fig. 8 (a), with the single parasite face in Fig. 8 (b) does not generate subset volumes. This is due to the inner loop edges and faces whereby the bounding parasite edges do not partition the top, bottom and inner loop faces into two subsets, and as a result the face loops on either side of the parasite boundary share certain faces and the volume cell ‘b1’ remains intact. However, the parasite face is added to the bounding topology of the host volume cell, oriented in both the positive and negative direction to maintain a valid configuration, as shown in the topological graph of ‘b1’ in Fig. 8 (c). The addition of a second parasite face, Fig. 8 (d), partitions the top ‘f5’, bottom ‘f4’ and inner loop ‘f7’ faces and generates two distinct face loops either side of the parasite boundary, thus partitioning the volume into the subset volumes ‘b2’ and ‘b3’ shown. Non-manifold conditions are considered to inform the edge-face traversal process not to include non-manifold edges. This enables the use of multiple parasite faces. Fig. 8 (e) and (f) show the addition of other parasite faces to decompose the subset volumes and their boundaries further and create the O-grid decomposition that can be used to generate a hex mesh around the hole. Thus, virtual operations are able to be used for existing virtual subset, superset and parasite entities which is an essential aspect of any virtual decomposition workflow, as shown in Fig. 8 (c), where subset volumes and faces are recursively partitioned. This is achieved by robustly managing the virtual and topological relationships and guaranteeing a valid topological description of a virtual entity is created that includes the correct relative orientation attributes.

It is worth pointing out that manifold modelling environments cannot manage the non-manifold conditions due to the addition of a single parasite face that does not partition the volume, Fig. 8 (b), resulting in errors when attempting to directly modify the geometry. Conditions such as these internal faces are easily represented in a virtual topology environment as a manifold geometric definition is not necessary. This flexibility allows analysts to generate their desired analysis topology using simple operations.
Based on other requirements, such as the extraction of thin regions for hex meshing (section 4.2), it may be necessary to use multiple connected parasite faces to decompose a volume cell, Fig. 9. As the virtual representation does not need to maintain a valid geometric definition it can directly represent non-manifold conditions like the presence of dangling faces or edges, Fig. 9 (b), within their respective parent volumes or faces. This enables multiple parasite faces to be used to decompose a volume cell as shown in Fig. 9. Parasite face loops are constructed by finding the common boundary between adjacent parasite faces, where no free edges exist in the loop, such as in Fig. 9 (d) and (c). Free edges are edges bounding a parasite face but no other face. Their presence informs the process that the volume has not been partitioned. Completing the parasite face loop enables the traversal process to begin to determine if the domain is partitioned, Fig. 9 (d). In this example...
two subset volumes are created representing a thin region, Fig. 9 (d) right, and a block topology type region, Fig. 9 (d) left. Topological traversals are utilized to assign orientations between multiple connected parasite faces and edges. These orientations enable the vertex corner and edge dihedral angles to be correctly identified, especially where parasite faces have no underlying surface definition.

4. Virtual topology operations for meshing

In this section examples of geometry clean-up and decomposition are provided, using the virtual topology operations in the previous section. The work detailed in this section has been implemented as a C# plug-in for Siemens NX, where a generic data structure in the form of a relational database is used to store the model topology and associated information as described in [17] and shown in Fig. 10 for the extraction of topology from Siemens NX. Extracting the initial model topology into this generic data structure enables it to be interrogated and manipulated to execute virtual topology operations, see process in Fig. 10. Each entity in the model is extracted along with their manifold dimension (0 for vertices, 1 for edges, 2 for faces and 3 for volumes) and a unique identifier (point lying inside the boundary of an entity). The topological connectivity and relative orientations are extracted from a CAD model automatically along with all vertex and edge classifications which are used for geometry clean-up and to help identify if a specific meshing strategy can be assigned to a volume cell. Vertex classifications define the angle between the bounded edges meeting at each vertex bounding a face, while edge classifications define the edge dihedral angle. These metrics are extracted during the initial topology extraction phase and are updated and re-calculated as the virtual representation is generated. Having a robust link to the NX model topology enables the NX manifold environment to exploit non-manifold conditions within the virtual representation. Non-manifold interface information is linked to the original manifold CAD model in Siemens NX through topological and virtual dependencies and stored as attributes in the relation database. These are assigned as name attributes to CAD entities and can be accessed from within NX. If utilizing other CAD or CAE packages, in the absence of name attributes the identifying point defined within the original topology is a robust way of tracking entities between packages.

---

**Fig. 10** Topology extraction, virtual decomposition and meshing flowchart for Siemens NX to ICEM CFD
4.1. Geometry clean-up example

Geometry clean-up operations attempt to remove features that can cause problems during mesh generation and cause poor quality elements to be formed. Clean-up decisions are based on geometric reasoning criteria (edge dihedral angle, edge length, face width, curvature etc.) adhering to predetermined mesh metrics (target element size, element angles etc.). Here a simple automated clean-up operation based upon edge dihedral angles is described.

Fig. 11 (a) Original design topology; (b) analysis topology after ignoring edges with a specific dihedral angle.

Edges to ignore are selected if they have a dihedral angle within 10% of 180 degrees, meaning that nodes do not need to be placed along these edges. For the model in Fig. 11 the selection returns 154 edges to be ignored from the original model topology, Fig. 11 (a), which are then provided as the input to the virtual merge operation described in Section 3.1. For the model in Fig. 11 the automated operation is executed in 2 seconds (on 64-Bit 2.8GHz Intel Core i7 CPU with 16GB RAM) and merges 59 faces and 28 edges to form 6 superset faces and 12 superset edges, Fig. 11 (b), where the ignored edges are faded out. The purpose of this example is to demonstrate the robustness of the virtual merge operations using a set of ignored edges as input. The generic nature of the procedure enables the input to be provided from any source, i.e. geometric reasoning operations built into an existing CAE package.

4.2. Thin-sheet region isolation through virtual decomposition

One approach for decomposing a complex domain for hex meshing is to isolate thin-sheet regions (large lateral dimensions relative to thickness) as separate volume cells [18, 19]. The hex meshing problem is simplified in thin-sheet regions where a quad mesh generated on a top or bottom face is swept through the thickness direction to create Hex elements. The thick-thin and virtual topology tools have been developed as plug-ins for Siemens NX. Using the direct decomposition approach certain thin-sheets are not extracted due to tolerance issues when generating the cutting faces [19]. Such issues can compromise the partitioning of subsequent thin-sheet regions, introduce sliver entities and reduce the overall effectiveness of the approach as associations to the base geometry are instantly lost.

The thick-thin algorithm [19] uses the NX mid-surface tool to identify face-pairs, which are the opposing faces bounding a thin-sheet region. Face boundaries are discretized and to calculate intersection regions between the boundaries to define thin-sheet regions. Parasite faces are generated from the opposing boundaries and are used to virtually partition the domain. At this stage no surface definition is required for the parasite face, only the simple geometry of the bounding edges is generated.

A simple example of the thin-sheet identification and virtual decomposition process is shown in Fig. 12. The edges on opposite sides of the thin-sheet region are defined as bounding edges of the parasite face and provided by the thin-sheet identification tool as the input to the virtual decomposition, Fig. 12 (b). These parasite bounding edges are provided along with their host face in the original topology. Virtual topology relationships are used to identify the new virtual host from the original input host. As the decomposition progresses this allows the appropriate faces to be partitioned using the parasite bounding edges and the analysis topology to be maintained. The wall edges through the thickness of the thin-sheet region are automatically generated within the virtual decomposition tool, where their host entity is identified and partitioned if necessary, Fig. 12 (c). Wall edge hosts are defined as the common bounded face of the end vertices of the input bounding parasite edges. Once all lower host topologies are partitioned the volume cell is virtually decomposed, Fig. 12 (d), into a thin-sheet and residual region.
Fig. 12 (a) Original topology; (b) parasite face bounding edges highlighted; (c) wall edges highlighted; (d) subset volume cells.

Fig. 13 (a) Original casing component; (b) thick-thin virtual decomposition.

Fig. 13 shows the thin-sheet virtual decomposition of an aero-casing component. 88% of the component is recognized as thin-sheet and highlighted grey, the residual regions highlighted black and virtual partitioning faces inset, Fig. 13 (b). The virtually decomposed representation is completely linked to the original component model and can be viewed and interacted within the NX environment. Virtual edge geometry is created for subset, superset and parasite edges and for visualization purposes. Surface geometry is not required for any virtual faces.

4.3. Identification of meshing strategies in the presence of virtual topology

The analysis topology description enables the use of simple interrogations to determine if either a mapped, swept or mid-point subdivision meshing approach can be applied to a volume cell. The interrogation is automatically executed using SQL queries on the simplified analysis topology. The analysis topology is associated with the original topology in an additional table in a relational database. Topological queries are considered, alongside criteria such as edge dihedral angles and vertex corner angles, when identifying the meshing strategy for different regions.

A mapped meshing scheme can be utilized for volumes with a logical block topology consisting of 6 faces, 12 edges and 8 corner vertices. Criteria for a volume cell to be map-able dictates all edges must be convex and all faces must be map-able. A face is considered map-able if it consists of four logical edges and four logical corner vertices where a single hex element will appear in the mesh pattern at each vertex and edge segment. Determining whether a volume cell is map-able is straightforward since the edge dihedral and vertex corner angles are maintained as attributes throughout the virtual operations described. A structured hex mesh generated for map-able volume cells uses opposing edges information to assign division numbers.

Volume cells that cannot be map meshed may be applicable for mid-point subdivision meshing if the cell is convex and contains all tri-valent vertices, Fig. 14 (a). Unlike mapping methods this scheme requires the cell to be partitioned into $n$ map-able blocks, where $n$ is the number of vertices in the volume cell, Fig. 14 (c) [20]. This
is an automatic procedure where the volume is decomposed using a series of four-sided faces bounded by edges generated from edge mid-points to face mid-points (black edges in Fig. 14 (b)) and from face-mid-points to volume center (dashed edges Fig. 14 (b)). In this work this step is carried out via the virtual decomposition. This decomposition contains mesh line singularities where an internal edge valence is not referenced by four hex elements and represents an unstructured portion of the mesh. Placement of these singularities is the root of the auto-Hex meshing problem and is used to help define Hex mesh topology and sizing amongst other properties. Using mid-point subdivision the line singularities are generated between the volume center and the mid-points of the bounding faces. The edge division numbers returned from a linear integer-programming routine help define the edge mid-points, face-midpoints and volume center positions as they are not strictly required to lie at the so-called mid-points. For mid-point subdivision schemes the edge division numbers can be found by providing only the radial edges, dashed edges Fig. 14 (b), as input to the integer-programming routine [21,22]. A simple topological query is used to identify these radial edges where they are the edges shared by more than two subset volume cells.

For certain classes of geometry swept meshing schemes simplify the 3D Hex meshing problem into the 2D domain. Sweep-able volume cells are bounded by a loop of map-able wall faces bounded by a source and target face, Fig. 15. The detection of sweep-able volume begins by classifying the map-able faces bounding the volume, Fig. 15 (b). These map-able faces are grouped into loops of connected map-able faces through their common edges, highlighted black in Fig. 15 (b). For a closed loop of map-able faces each map-able face is bounded by two other map-able faces. The uncommon edges, dashed in Fig. 15 (b) between the closed loop of map-able faces are used to identify the source and target faces, which are each bounded by a distinct loop of uncommon edges, Fig. 15 (c), ensuring both source and target faces are topologically identical. Hex meshes can be generated on swept volume by meshing the source face with quadrilateral elements and sweeping towards the target face along the map-able wall faces. The line singularities in sweep-able domains run along the sweep direction.

The subset volume cells from the virtual thin-sheet decomposition from Fig. 13 were automatically interrogated to identify an appropriate meshing scheme. The results are shown in Fig. 16 with 77% of the original volume map-able and 21% sweep-able. The remaining 2% of the volume cannot be swept, mapped or meshed using mid-point subdivision and would require further manual decomposition to generate mesh-able volumes.
4.4. Exploiting virtual decomposition for mesh generation

Extensibility of this approach is demonstrated by exploiting the virtual decomposition, Fig. 17 (b), generated from the design model in Siemens NX, Fig. 17 (a), to output the required information for multi-block meshing tools, in this instance ICEM CFD, see the process in Fig. 10.

Virtual topology relationships are used to extract block definitions and interfaces, Fig. 10, and automatically specify the edge constraints necessary to determine the edge division numbers for meshing. Fig. 17 (c) shows highlighted edges in the block decomposition where the division number assignment must be equal for each highlighted edge. Once the constraints for the remaining edges in the model are identified integer programming routines [21, 22] are used to assign the division numbers.

Alongside edge division assignment the block definitions and interfaces extracted from the virtual block decomposition are used to determine the block meshing recipe to allow it to be replicated and subsequently meshed in ICEM CFD, Fig. 10. Block interface information is used to direct the meshing recipe, where blocks with partial interfaces are generated first in a bottom-up blocking approach, Fig. 18. The steps in the blocking recipe are shown in Fig. 18 with the newly added block in each step highlighted black. Where appropriate face splits, highlighted red in Fig. 18, are used to generate and capture the partial interfaces for the subsequent blocks in the meshing recipe. The entire meshing recipe is determined from a series of topological queries carried out on the virtual block decomposition utilizing the analysis topology and virtual dependencies stored in the relational database, Fig. 10.

ICEM blocking and mesh generation is automated using the blocking recipe output from the virtual topology tool which includes block corners and positions for each block, block face split instructions, calculated edge division numbers and the associativity to the underlying geometry. The associativity to the geometry is easily extracted by tracking the virtual dependencies and topology back to the original extracted topology, see Fig. 10. The results for this example are shown in Fig. 19 where different input target element sizes are specified to
generate the meshes in Fig. 19 (b) and (c). Whilst this is one possible avenue for meshing the virtual decompositions produced in this work further effort is required to enable more complicated domains to be meshed.

5. Discussion

This work has shown how an analysis topology defined using virtual topology operations can be linked to, but stored separately from, the original CAD model. Maintaining the virtual representation in this manner enables multiple analysis topologies to reference a single base topology. Creation of the analysis topology enables a non-manifold representation to be created, which maintains the links between adjacent sub-cells within the virtual decomposition, without needing a non-manifold CAD modelling environment. For example, the implementation within Siemens NX described here makes use of the non-manifold common faces to assign mesh mating conditions. A major contribution is the ability to connect this virtual topology implementation to existing CAD and CAE packages. In this work the compatibility between the generic virtual topology tool linked to the Siemens NX to generate a virtual decomposition, and ICEM CFD which is used to mesh the virtual decomposition has been demonstrated. Providing the capability to interact with multiple different design and analysis packages is a considerable step towards more automated workflows where tools can be selected based on their functionality as opposed to their compatibility.

Section 4 demonstrates the virtual topology operations on geometric models of industrial complexity, where virtual merge operations are used for geometry clean-up and virtual splits are used for thin-sheet removal within complex domains. A major benefit is that the virtual representation is completely linked to the original model topology. Therefore, virtual operations can be easily and (usually) automatically updated after small parametric design changes. This is in contrast to situations where real geometric modifications have been made, where the links to the original model are lost making it difficult to perform automatic updates after even the smallest modifications. The virtual merge operations are described for faces and edges of single components but need extended to merge adjacent volume cells of multi-component assemblies. The actual merging of adjacent volume cells sharing exact boundaries is a simple extension to the work described in this paper. The difficulty is to determine the connection between components to create exact interfaces between components within the specific analysis context. This might be achieved by generating a tolerant virtual representation to treat gaps and overlaps in assembly configurations.

Geometric issues in single component definitions can be common in product development workflows and can result from CAD translation errors, poorly constructed models or a combination of both. Addressing issues such as gaps, overlaps, sliver faces, missing faces and self-intersecting surfaces can be challenging from a geometric viewpoint. However, as the ultimate goal in many cases is to derive a fit-for-purpose mesh, the challenge is to adapt a geometric model so that it is suitable for the meshing algorithm. Therefore, as one of motivations of this work has been to generate relatively coarse Hex meshes for non-linear transient analyses, the need to geometrically fix small gaps, Fig. 20, is reduced as the gap is considerably less than the target element size. To this end it is sufficient to make the model in Fig. 20 ‘topologically’ watertight in order to create the desired mesh. The free edges bounding the gap are easily identified as they bound only a single face, allowing the topology to be made watertight by simply removing one edge from the analysis topology and replacing it with the residual edge in the bounding topology of its bounded face. These topological swaps can be realized for other clean-up operations, such as missing faces or duplicate edges. Nevertheless, declaring a geometric model as fit-for-meshing-purposes remains subjective and is influenced primarily by the meshing process leaving ‘geometrically’ watertight models typically demanded. Consequently in order to gain maximum benefits from
virtual representations future research in this area should focus on adapting mesh generation algorithms to operate in the presence of virtual topology [23].

![Fig. 20 Virtual topology gap treatment (a) Original CAD topology; (b) Topologically watertight using edge removal.](image)

Whilst significant progress has been made to allow tools to operate in the presence of virtual topology, there still remains work to be done. For example, using the virtual merge operations to merge certain faces, i.e. with the same underlying surface definition that are bounded by edges with a dihedral angle close to 180 degrees, prior to implementing the thin-sheet removal tool would reduce the complexity of the identification and partitioning process. The same proportion of the model would remain recognized as thin-sheet regions due to the upfront merging operations essentially treating adjacent thin-sheet regions as one and reducing the number of partitions required and the overall decomposition time.

Since the mesh scheme identification algorithms consider only topological characteristics of a volume along with vertex and edge classifications there will be instances where geometric reasoning needs to be implemented to take into account properties such as varying edge dihedral angles or surface curvature. However, in this work it is assumed that since the model has been initially interrogated during the thin-sheet identification process, the thin-sheet regions and their adjacent regions can accurately be assessed using the topological approach undertaken. Manual virtual decomposition methods can be utilized for the residual regions assigned no meshing strategy. The virtual topology tool will accept two bounding edges of a parasite face as the manual input and will automate the partitioning of all lower bounding topologies and the addition of the remaining edges bounding the parasite face, as described in Fig. 12. This releases the analyst from substantial effort required to generate partitioning geometry. In addition the link between the virtual decomposition to the underlying geometry is automatically maintained unlike manual blocking tools such as ICEM CFD where associations between the block topology entities to the original model entities needs manually specified as the blocking is overlaid on the geometry.

Regions may also be considered as map-able where a logical block face may be represented by several faces. Such a scenario can be seen in the subset volume in Fig. 21 (c) which can be treated as a map-able region since there are no mesh singularities. This removes the need to propagate the block pattern through the virtual decomposition and reduces the burden on the analyst. The subset volume is essentially a sweep-able block where the block faces with the internal imprints is meshed first. Therefore, these imprinted regions may exist on source and/or target faces of sweep-able block regions. For more complex scenarios further work is required to automatically propagate the blocking to progress from the initial coarse block decomposition using a series of merge and imprint operations to achieve a more readily mesh-able block decomposition. In addition, these ideas need extended to treat 1-n, n-n sweeps and more complicated sub-mappable regions which can be treated as sweep-able blocks with generic approaches to automate their virtual decomposition process.

6. Conclusion

This paper has described a generic approach for executing virtual topology operations. Merge and split operations have been described in detail for all topological entities including the partitioning of volume cells.
Descriptions of the topological queries required to generate the analysis topology are provided for each virtual merge or split operation. Managing the virtual and topological dependencies help maintain a valid topological description, which includes orientations, within the virtual representation and automatically retain links to the underlying geometry after virtual operations are performed. This topological consistency enables boundary traversals to be used to virtually decompose the domain of interest where virtual operations are executed successfully on both original and virtual entities. A robust hierarchical virtual structure enables the analyst to prepare the analysis model in any desired fashion. Virtual merge and split operations have been demonstrated on realistic geometric components and can be utilized in either manual or automated workflows where the partitioning instructions are delivered from an upstream tool, such as the thin-sheet identification tool.

The analysis topology description is managed alongside the original model topology, facilitating complete associativity between the representations and connecting the generic virtual representation to existing CAD packages. Manifold modelers can utilize the non-manifold topology in the virtual domain. This enables model interrogations and modifications to be carried out on the analysis topology without affecting the original topology. To this end a process has been described where volume cells are automatically interrogated to determine whether a specific meshing scheme can be assigned to it. Substantial work needs to be done to develop more tools to operate in the presence of virtual topology, especially meshing algorithms for meshing virtual cells.
