Abstract

Posttraumatic stress, depression, and anxiety symptoms are common outcomes following earthquakes, and may persist for months and years. This study systematically examined the impact of neighborhood damage exposure and average household income on psychological distress and functioning in 600 residents of Christchurch, New Zealand, 4-6 months after the fatal February, 2011 earthquake. Participants were from highly affected and relatively unaffected suburbs in low, medium and high average household income areas. The assessment battery included the Acute Stress Disorder Scale, the depression module of the Patient Health Questionnaire (PHQ-9), and the Generalized Anxiety Disorder Scale (GAD-7), along with single item measures of substance use, earthquake damage and impact, and disruptions in daily life and relationship functioning. Controlling for age, gender and social isolation, participants from low income areas were more likely to meet diagnostic cut-offs for depression and anxiety, and have more severe anxiety symptoms. Higher probability of acute stress, depression and anxiety diagnoses was evident in affected versus unaffected areas, and those in affected areas had more severe acute stress, depression and anxiety symptoms. An interaction between income and earthquake effect was found for depression, with those from the low and medium income affected suburbs more depressed. Those from low income areas were more likely post-earthquake to start psychiatric medication and increase smoking. There was a uniform increase in alcohol use across participants. Those from the low income affected suburb had greater general and relationship disruption post-quake. Average household income and damage exposure make unique contributions to earthquake-related distress and dysfunction.

Keywords: earthquake, distress, exposure, socioeconomic status
The impact of average household income and exposure to neighborhood damage on post-earthquake psychological distress and functioning: A community study following the Christchurch 2011 earthquake

In the days, weeks, and months following a disaster, survivors can struggle to regain a sense of who they were before the event, as they try to adapt to various personal and resource losses, and to emotional reminders of their experiences (Bonanno, Brewin, Kaniasty, & La Greca, 2010; Kar & Bastia, 2006; McFarlane, 1988; Norris et al., 2002). As an unpredictable natural disaster, earthquakes especially test the capability of individuals and communities to cope with unexpected mass upheaval, disruptions and loss (Bödvarsdóttir & Elklit, 2004).

The prevalence of psychological distress like depression, anxiety and posttraumatic stress after earthquakes ranges between 6% and 67%, depending on whether assessment examined symptoms or disorders, and when the measures were taken (Armenian et al., 2002; Carr et al., 1995; Kiliç et al., 2006; Sharan, Chaudhary, Kavathekar & Saxena, 1996; Zhou et al., 2013). For example, rates of posttraumatic stress disorder and major depressive episodes were 39% and 18%, respectively, when assessed 20 months after the Marmara earthquake in Turkey (Salcıoğlu, Başıoğlu, & Livanou, 2003). Symptoms often reduce over time, but for a considerable number of individuals they linger for months and years (Carr et al., 1995; Goenjian, Steinberg, Najarian, Fairbanks, Tashjian, & Pynoos, 2000; Kuwabara et al., 2008; Zhou et al., 2013). Carr et al. (1995) suggest that ongoing psychological symptoms following earthquakes are associated with the possibility of repeated aftershocks (Dorahy & Kannis-Dymand, 2012) and continued disruptions associated with loss of property, displacement, domestic relocation, and infrastructure redevelopment.
Earthquake-related symptoms may be particularly elevated among those with greater exposure to disruptions and displacement (Carr et al. 1997; Norris et al., 2002), such that those more physically affected by the earthquake (e.g., loss of house, displacement) have greater psychological symptoms (Dorahy & Kannis-Dymand, 2012; Lima et al., 1989). Carr et al. (1995) reported that people with high levels of exposure to the 1989 Newcastle (Australia) earthquake had more general and posttraumatic symptom distress than those with lower exposure levels. Disruption (e.g., loss of home, displacement, change of employment) had a greater impact on general psychological distress (e.g., mood and anxiety symptoms) than posttraumatic distress. Yet, experiences of threat (e.g., personal injury, experiences of danger) had a similar elevated impact on both general and posttraumatic distress. General and posttraumatic distress were predicted by gender (female) and exposure, while general distress was further predicted by reduced social support, and posttraumatic distress by age (being older). Interestingly, perceived social support had no impact on posttraumatic stress symptoms at 6 months.

Other work has supported the link between distress and earthquake exposure in the form of personal losses and community destruction (Sattler, Glower de Alvarado, Blandon de Castro, Van Male, & Vega, 2006; Sharan et al., 1996). A study 7 months after the magnitude 8.0 Sichuan (south-western China) earthquake (2008) found that loss of friends or neighbors, residential house damage or collapse, and proximity to the epicentre, were significant predictors of severe mental health problems among survivors (Chan et al., 2011). Losses may lead to a decline in social networks and support in affected communities which precedes any decline in psychological well-being, including the onset or worsening of depression (Kaniasty & Norris, 1993).
In short, factors associated with increased risk of earthquake-related distress include being female, experiencing displacement or relocation as a result of the earthquake, having heightened exposure to the aftermath, experiencing loss and destruction of a range of resources, having reduced social support, fearing ongoing earthquakes, and being older (Armenian et al., 2002; Bland et al., 1997; Carr et al., 1995; Dorahy & Kannis-Dymand, 2012; Kiliç et al., 2006; Lima et al., 1989; Najarian, Goenjian, Pelkovitz, Mandel, & Najarian, 2001; Sattler et al., 2006; Shindo, Kitamura, Tachibana, Honma, Someya, 2012; Zhou et al., 2013). Moreover, having less access to material and emotional resources heightens risk (Lima et al., 1989).

Several of the above factors associated with earthquake distress may be accounted for by Hobfoll’s conservation of resources theory. This argues that individuals are motivated to accrue, cultivate and protect resources they attribute value to (e.g., Hobfoll, 2001, 2011). Resources fall into several categories, including object (e.g., house, car), condition (e.g., time with loved ones), personal characteristics (e.g., sense of optimism) and energy (e.g., adequate food). The loss of valued resources represents a central and salient feature in the production of stress and distress, which is more pertinent to psychological functioning than resource gain (Hobfoll, 2001). As such, people heavily affected by earthquake-related damage, destruction and loss should experience more distress than those less affected by these factors. Moreover, those heavily affected who have less financial assets are likely to experience greater distress as they lose the fewer resources they have.

The current study systematically examined the impact of average household income and degree of exposure to neighborhood damage on psychological outcome 4-6 months after the 2011 6.3 magnitude earthquake in Christchurch (New Zealand) which killed 185 people. This fatal earthquake occurred in the context of a prior 7.1
magnitude earthquake (September 4th, 2010) and multiple, ongoing aftershocks that preceded and proceeded that event. Participants were residents of highly affected suburbs in low, medium and high average household income areas of Christchurch who were matched with residents of relatively unaffected suburbs from the same average income group. Affected suburbs experienced a range of problems including major property damage or loss, severe soil liquefaction (rising silt and water residue), and significant loss and disruption in utilities such as water, sewage and electricity. The primary outcome variables of anxiety, depression and posttraumatic stress symptoms were measured, as these are the most common symptoms following disasters (e.g., Kar & Bastia, 2006; Kiliç et al., 2006; Lima et al., 1989; Madianos & Evi, 2010; Norris, Perilla, Reid, Kanisty & Lavizzo, 1999). Substance use and both general and relationship functioning were also examined.

Drawing on Hobfoll (2001) and following previous work (e.g., Dorahy & Kannis-Dymand, 2012), participants in suburbs most physically affected by the earthquakes where expected to demonstrate greater symptom distress than those in relatively unaffected suburbs. In addition, those in the lowest income area, who were severely affected by the earthquakes, were predicted to have the most distress. Post-earthquake substance use was expected to be higher in the low income areas that were physically affected. Moreover, in these participants general and relationship functioning were expected to be reduced. Gender, age, and lack of social support were used as covariates to further isolate the influence of physical damage/earthquake effect and income level, due to their association with post-earthquake variables (e.g., Sattler et al., 2006).

Method

Participants
Six hundred participants were recruited for this study and included 100 residents from each of six different suburbs of Christchurch. Suburbs sampled were chosen based on 1) degree of physical destruction caused by the earthquake (earthquake affected or relatively unaffected) and 2) average household income. Three of the six suburbs were severely physically affected by the earthquake, sustaining large-scale property loss and loss of utilities (water, sewage, electricity) for weeks and sometimes months. Many homes in these areas were ‘red stickered’ (building not safe to enter or occupy) and some-to-much of the land was ‘red zoned’ (land likely unsuitable for continued residential occupation). These three suburbs reflected low, medium and high average household income areas. Determination of the demographic characteristics and average household income of each suburb was based on 2006 census data (www.stats.govt.nz/Census/2006CensusHomePage.aspx).

Each of these three affected suburbs was matched to a suburb which was relatively unaffected by the earthquake, had the same demographic variables (e.g., number of people in suburb, average age and gender) and same average household income. The matched suburbs experienced comparatively lower level of damage to homes and properties, and had minimal loss of utilities. Thus, based on damage and income level, the six suburbs could be defined as: Affected Low income (AL), Relatively unaffected Low income (RL), Affected Medium income (AM), Relatively unaffected Medium income (RM), Affected High income (AH), and Relatively unaffected High income (RH). The low income suburbs had populations of around 3,200 people, with a median individual yearly income of approximately $22,000. The medium income suburbs had populations of around 3,600 people, with a median individual yearly income of approximately $26,000. The high income suburbs had
populations of around 3,800 people and a median individual yearly income of approximately $33,500.

The total sample (N=600) ranged in age from 18-90 years (M = 49.69 years; SD = 15.79). Mean age appeared to increase with income level, F(2, 595) = 10.41, p<.001; the high income areas had the highest mean age (M = 50.49 years; SD = 13.89), followed by the medium (M = 48.48 years; SD = 17.65) then the low income (M = 45.73 years; SD = 14.86) suburbs. The communities did not differ in terms of gender with the overall sample consisting of 218 males (36.3%) and 382 (63.7%) females.

In total 2650 households were approached resulting in a valid response rate of 22.6%. The households that did not respond were categorized as declining to participate (10.9%) or vacant/no answer (66.5%). Table 1 shows the response rate by suburb. There was a significant association between declining involvement and average suburb income, \( \chi^2(2, n=2650)=41.70, p<.001; \phi=.12 \), with an increased frequency of households in the low (9.7%) or medium (9.2%) income areas declining compared to the high income suburbs. The phi coefficient indicates the effect size was very small. There was a significant association between declining participation and neighborhood damage, \( \chi^2(1, n=2650)=33.13, p<.001; V=.11 \), with 7.1% more households in the relatively unaffected area declining to take part. Again the effect size (Cramer’s V) was very small.
The structure and content of the survey was initially developed as part of an earlier study examining the September 2010 magnitude 7.1 earthquake in Christchurch (Dorahy & Kannis-Dymand, 2012). It contained the Acute Stress Disorder Scale (ASDS; Bryant, Moulds, & Guthrie, 2000), the Patient Health Questionnaire’s 9-item depression module (PHQ-9; Spitzer, Kroenke, & Williams, 1999), and the Generalized Anxiety Disorder-7 scale (GAD-7; Spitzer, Kroenke, Williams, & Löwe, 2006). For this study all items were anchored to currently occurring symptoms starting since the February 22nd 2011 earthquake and ongoing aftershocks. The ASDS was administered first, followed by the PHQ-9, and then the GAD-7.

Following administration of the standardized measures, age and gender were recorded and participants were asked single item questions regarding degree of social isolation, and changes in medication, alcohol, cigarette consumption, and recreational drug use since the February earthquakes. The response format, anchored to increases in substances, started with ‘not applicable’ and then ranged on a 5 point scale from ‘not at all’ to ‘a significant amount’. Participants were also asked dichotomous response (‘yes/no’) questions regarding whether they lived without electricity, water, and sewage for two or more days following the earthquake, whether they had to move house as a result of the earthquake and whether they sought health and social service support post-earthquake. They also responded on a dichotomous scale to whether they had lost anything (e.g., house, family member, job) from the earthquake.

**Functioning**

Questions addressing daily and relationship functioning were also administered. These were assessed on a 0 (N/A) to 5 (extreme) point scale with participants asked about the degree to which the earthquakes had disrupted their work,
household tasks, leisure activities, family unit, and relationships with partner, children, and family/friends. An exploratory factor analysis with principal axis factoring extraction was conducted on the seven functioning items. Both the scree plot and the Kaiser criterion suggested there were two distinct factors with no cross loading items. The first factor consisted of four items relating to disruption to relationships with children, the family unit, partner and extended family/friends (factor loadings ranged from .47-.81), and was named relationship functional disruptions. The second factor contained three items relating to disruption in social and leisure activities, household tasks and work outside the home (factor loadings ranged from .46-.70), and was named general functional disruptions.

 DISTRESS markers

The ASDS is a 19-item inventory based on DSM-IV (American Psychiatric Association, 1994) criteria for acute stress disorder, which is widely used in research and clinical settings (Bryant, Moulds & Guthrie, 2000). Items assess dissociation (5), re-experiencing (4), avoidance (4), and arousal (6) symptoms on a Likert-type scale ranging from 1 (not at all) to 5 (very much). A diagnosis of acute stress disorder can be estimated if scores on the dissociation subscale are greater than 8 and the cumulative scores of the remaining 3 subscales are greater than 27 (Bryant et al., 2000; Bryant & Harvey, 2000). The ASDS has demonstrated excellent psychometric properties, with Cronbach’s alphas higher than .8 for total and subscale items (Bryant et al., 2000). A more recent study with Chinese earthquake survivors found that the four-factor structure for the ASDS was consistent with DSM-IV symptom clusters (Wang, Li, Shi, Zhang & Shen, 2010). The ASDS, which requires a time frame of no longer than a month since the trauma, was included in the study because large earthquakes were continuing (e.g., two struck on June 13th 2011, measuring 6.3 and
5.9). Thus, for many, trauma stimuli were still acute and ongoing. The ASDS also provides a good indication of posttraumatic stress disorder symptoms as it measures the three symptom types of DSM-IV PTSD.

The PHQ-9 reflects the nine items on the larger PHQ designed to assess depression. Participants rate how much they were bothered by each item on a 4-point Likert scale from 0 (not at all) to 3 (nearly every day). It has been used widely in primary care, specialist medical settings and the general population to offer both a severity rating for depression and a probable diagnosis (Spitzer et al., 1999). The continuous scale assessing severity of depression symptoms ranges from 0-27, with scores above 5, 10, 15 and 20 representing mild, moderate, moderate-severe and severe levels of depression, respectively (Kroenke & Spitzer, 2002; Kroenke, Spitzer, & Williams, 2001; Kroenke, Spitzer, Williams & Löwe, 2010). A probable diagnosis of major depressive disorder can be made if participants endorse 5 or more of the 9 symptoms as experienced ‘more than half the days,’ but the 9th item, assessing for suicidal ideation, is included if endorsed ‘several days.’ In addition, one of the first two items, assessing mood and loss of interest, must be endorsed for a probable diagnosis of major depressive disorder (Kroenke et al., 2010). The PHQ-9 is a reliable and valid measure of depression severity (Kroenke et al., 2001, 2010) and is highly correlated with Major Depressive Episode and Major Depressive Disorder as diagnosed with the Structured Clinical Interview for DSM-IV (SCID; Cannon, Tiffany, Coon, Scholand, McMahon, & Leppert, 2007).

The GAD-7 scale is a seven item measure of general anxiety (Spitzer, Kroenke, Williams, & Lowe, 2006) based around the DSM-IV diagnostic criteria for generalized anxiety disorder (GAD). Whilst it was primarily designed to assess GAD, it has been found to be a good screen for other anxiety disorders (Kroenke et al.,
Items assess how frequently participants are bothered by specific anxiety symptoms. Responses are made on a 4-point Likert scale ranging from 0 (not at all) to 3 (nearly every day). Summed scores range between 0 and 21, with scores over 5, 10, and 15 reflecting mild, moderate and severe anxiety, respectively (Kroenke et al., 2010; Löwe et al., 2008; Spitzer et al., 2006). Scores over 8 are thought to be indicative of an anxiety disorder (Kroenke, Spitzer, Williams, Monahan, & Löwe, 2007), with Ebell (2008) suggesting that a cut-off of nine provides better detection of those with an anxiety disorder (sensitivity) while not compromising the ability to rule out those without an anxiety disorder (specificity). Thus, we used a cut-off of nine to detect an anxiety disorder. The GAD-7 has good reliability and validity as a self-report measure of anxiety in the general population (Löwe et al., 2008; Spitzer et al., 2006). It was used here as an efficient and valid assessment of anxiety severity (Spitzer et al., 2006).

**Procedure**

A door-to-door survey methodology was utilized, with participants ‘cold called’ and assessed at their own home. Following informed written consent, participants were read each question by the interviewer. The survey took approximately 20-30 minutes to complete. Upon completion, participants were debriefed, asked if they would like to participate in a follow-up study in approximately 5 months, and were given an information sheet offering free support and counseling services in Christchurch along with several self-help educational resources. Data collection commenced 4 months after the February 22\(^{nd}\) earthquake and had a two-month window. Notably, shortly after the start of data collection 2 large aftershocks were experienced on the same day (June 13\(^{th}\), 2011, 1.00pm,
Magnitude 5.9; 2.20pm, Magnitude 6.4; [http://www.canterburyquakelive.co.nz/](http://www.canterburyquakelive.co.nz/). The study was approved by the University of Canterbury Human Ethics Committee.

**Analyses**

Associations between average income level (low, medium, high) and earthquake effect (relatively unaffected, affected) for the categorical variables of 1) diagnoses (acute stress, depression, anxiety) and 2) the use of prescription medicines were assessed with Pearson Chi-square tests (using Yates’ continuity correction for 2x2 contingency tables) with Cramer’s V and phi coefficients (as appropriate) as estimates of effect size. To test the differences and interactions between average income and earthquake effect on interval/ratio measures 2-factor multivariate analysis of covariances (MANCOVAs) were conducted. Separate MANCOVAs were conducted for the dependent variables of; 1) distress (acute stress, depression, anxiety) scores, 2) ASDS subscales, 3) substance use and 4) functioning scores. In each case age and gender were included as covariates. For the distress scores of acute stress, depression and anxiety, social isolation was introduced as an additional covariate (this variable was not related to ASDS subscales, substance use/drug use and functional disruption scores). MANCOVA was chosen to control for the family-wise error rate and take account of the theoretical and statistical relationships between the scales. Effect sizes were estimated with partial eta squared. All analyses were computed using the Statistical Package for the Social Sciences (SPSS Version 19).

**Results**

**Earthquake effects across suburbs**

Supporting the experimental differentiation between affected and relatively unaffected suburbs, 51% of those living in affected suburbs moved from their homes as a direct result of the earthquake, compared to 13% in the relatively unaffected suburbs, $\chi^2 (1, n=600)=96.58, p < .001; \phi=.40$. Those in high income (45%) suburbs
INCOME & DAMAGE EXPOSURE ON POST-EARTHQUAKE DISTRESS

reported moving house more than those in low (28%) and medium (24%) income suburbs, $\chi^2 (2, n=598)=22.75, p<.001; V=.20$. In terms of losing utilities (water, sewage, electricity), 94.7% of those in the affected suburbs responded affirmatively, compared to 45.2% in the relatively unaffected areas, $\chi^2 (1, n=599)=174.67, p < .001; \phi=.54$. Again, despite the overall high level of utility loss across the sample, the high income area (88%) was significantly more affected than the low (54%) and medium (68%) areas, $\chi^2 (2, n=599)=58.90, p<.001; V=.31$. Seeking health and mental health service following the earthquake was more prevalent in the affected suburbs (AL = 39%; AM = 35%, AH = 18%, total = 31%) versus the relatively unaffected areas (RL = 28%, RM = 12%, RH = 12%, total = 18%), $\chi^2 (1, n=598)=13.08, p < .001; \phi=.15$, and was more prevalent in low income (34%) compared to medium (25%) and high (15%) income areas, $\chi^2 (2, n=598)=18.64, p < .001; V=.18$. Seeking social services support was also higher amongst affected suburbs (96% vs 77%), $\chi^2 (1, n=594)=47.88, p<.001; \phi=.28$, while the high income areas (99%) were more likely to seek this support compared to the low (82%) and medium (79%) income areas, $\chi^2 (2, n=598)=36.66, p<.001; V=.25$.

**Diagnoses across suburb average income**

Table 2 shows the diagnostic cut-offs for acute stress disorder, depression and anxiety across suburb average income levels. The sample demonstrated prevalence rates of 41.2% for acute stress, 38.3% for depression, and 42.8% for anxiety. There was no significant association between acute stress diagnosis and income level. However, there was a significant association between depression diagnosis and income level, $\chi^2 (2, n=600)=13.72, p=.001; V=.15$, with higher levels of depression diagnosis in the lowest income (47.5%) compared to the medium (38%) or high (29.5%) income areas. When this trend was further explored in relation to depression
severity, significant associations between income level and both mild, $\chi^2 (2, n=600)=8.34$, $p=.025$; $V=.12$, and moderate depression, $\chi^2 (2, n=600)=9.53$, $p=.009$; $V=.13$ were evident. The highest reported incidence for mild depression was in the low income (30%), compared to the medium (19%) and high (20%) income areas. Similarly for moderate depression, the highest rates were reported in the low income (15.5%), compared to the medium (13%) and high (6%) income suburbs. There was no association between income level and either moderate-severe or severe depression; perhaps partly due to the low number indicating high depression levels (2% and 1.8% respectively).

A significant association was found between anxiety diagnosis and income level, $\chi^2 (2, n=600)=36.03$, $p<.001$; $V=.25$, with higher levels of anxiety diagnosis in the lowest income (59.5%), compared to the medium (38%) and high (31%) income areas. Further exploration found a significant association between mild anxiety diagnosis and income level, $\chi^2 (2, n=600)=29.35$, $p<.001$; $V=.22$, with higher levels in the lowest income (43%), compared to the medium (22.5%) and high (22%) income areas. A similar trend was observed for moderate anxiety, $\chi^2 (2, n=600)=8.02$, $p=.018$; $V=.12$, with higher levels in the low (15%), compared to medium (9.5%) and high (6.5%) income suburbs. There was also a significant association between severe anxiety diagnosis and income, $\chi^2 (2, n=600)=9.72$, $p=.008$; $V=.13$ but in this case the medium income had the highest score (7%), followed by the high (2.5%) and low (1.5%) income areas. Only 3.7% of the total sample reported severe anxiety.

---

**Diagnoses across Earthquake effect**
There was a significant association between acute disorder diagnosis and earthquake effect, $\chi^2 (1, n=600)=20.07, p<.001; \phi=.19$, with those respondents from the affected suburbs having a higher frequency of acute stress disorder (50.3%) than the relatively unaffected suburbs (32%; see Table 2). Similarly, there was a significant association between depression diagnosis and earthquake effect, $\chi^2 (1, n=600)=46.26, p<.001; \phi=.28$; affected suburbs had more respondents meeting cut-off for a depression diagnosis (52%) than the relatively unaffected suburbs (24.7%).

When this trend was further explored in relation to distress severity, similar significant associations were found for mild, $\chi^2 (1, n=600)=7.91, p<.005; \phi=.12$ and moderate, $\chi^2 (1, n=600)=28.29, p<.001; \phi=.22$, depression, with higher levels of mild (28%) and moderate (18.7%) depression in affected compared to relatively unaffected suburbs (18% & 4.3% respectively). There was no significant association between earthquake effect and either moderate-severe or severe depression.

Finally, there was a significant association between anxiety diagnosis and earthquake effect, $\chi^2 (1, n=600)=12.01, p<.001; \phi=.14$, with those from the affected suburbs having a higher frequency of anxiety diagnosis (50%) compared to the relatively unaffected suburbs (35.7%). There was no significant association between mild anxiety diagnosis and earthquake effect. However, earthquake effect was significantly associated with moderate anxiety, $\chi^2 (1, n=600)=7.2, p<.007; \phi=.11$, with higher rates in affected suburbs (13.7%) compared to relatively unaffected areas (7%). Similarly there was a significant association between severe anxiety and earthquake effect, $\chi^2 (1, n=600)=3.92, p=.049; \phi=.09$ with higher rates in affected suburbs (5.3% vs 2%).

The association of suburb income and earthquake effect with distress scores
Table 3 shows the descriptive and reliability statistics for stress, depression and anxiety measures for the total sample.

A 2-factor MANCOVA with the three distress scales (acute stress, depression & anxiety) as dependent measures revealed the significant covariates of gender, Pillai’s trace=.12; $F(3, 587)=25.74; p<.001; \eta^2_p=.12$, age, Pillai’s trace=.05; $F(3, 587)=9.46; p<.001; \eta^2_p=.05$, and social isolation, Pillai’s trace=.03; $F(3, 587)=25.74; p<.001; \eta^2_p=.03$. Furthermore there were significant multivariate main effects of income, Pillai’s trace=.06; $F(6, 1176)=5.80; p<.001; \eta^2_p=.03$, and earthquake effect, Pillai’s trace=.11; $F(3, 587)=24.00; p<.001; \eta^2_p=.11$. There was also a significant multivariate interaction, Pillai’s trace=.05; $F(6, 1176)=5.16; p<.001; \eta^2_p=.11$. Average income produced a significant main effect on anxiety scores, $F(2,589)=7.03; p=.001; \eta^2_p=.02$, with respondents from the lowest income areas reporting higher anxiety than the medium ($p=.005$) and high ($p=.003$) income suburbs (see table 4). Average income produced no main effect for acute stress or depression scores. The main effect for earthquake effect showed those living in affected suburbs had higher acute stress, $F(1,589)=31.07; p<.001; \eta^2_p=.05$, depression, $F(1,589)=72.10; p<.001; \eta^2_p=.11$, and anxiety, $F(1,589)=41.57; p<.001; \eta^2_p=.07$ scores.

The only significant interaction between average income and earthquake effect was on the depression scale, $F(2,589)=8.82; p<.001; \eta^2_p=.03$. Respondents from low and medium income areas living in affected suburbs had significantly higher depression scores ($p<.05$) than those from low and medium income areas living in
relatively unaffected suburbs. However, there was no significant influence of earthquake effect on depression scores in the high income suburbs.

---

**Average income and Earthquake effect on ASDS subscales**

A 2-factor MANCOVA with the 4 ASDS subscales (dissociation, intrusion, avoidance & arousal) as dependent measures revealed the significant covariates of gender, Pillai’s trace=.11; $F(4, 587)=18.29; p<.001; \eta^2=.11$ and age, Pillai’s trace=.04; $F(4, 587)=6.36; p<.001; \eta^2=.04$. Furthermore there were significant multivariate main effects of income, Pillai’s trace=.03; $F(8, 1176)=2.03; p=.04; \eta^2=.01$, and earthquake effect, Pillai’s trace=.71; $F(4, 587)=11.16; p<.001; \eta^2=.07$. There was no significant multivariate interaction. The only subscale that demonstrated a main effect on average income was dissociation, $F(2,590)=3.26; p=.039; \eta^2=.01$, with respondents from medium income areas ($m=10.46; SD=4.33$) having significantly higher mean dissociation scores ($p=.042$) than respondents from high income areas ($m=9.53; SD=4.16$). There were significant main effects for earthquake effect on dissociation, $F(1, 590)=33.13; p<.001; \eta^2=.05$; intrusions, $F(1, 590)=11.90; p=.001; \eta^2=.02$; avoidance, $F(1, 590)=4.38; p=.037; \eta^2=.01$ and arousal, $F(1, 590)=31.14; p<.001; \eta^2=.05$. Living in an affected area was related to significantly higher mean scores on all four ASDS subscales (see table 5).
The association of suburb average income and earthquake effect with substance use

No significant association was found between starting psychiatric medication and earthquake effect, with 7% of those in relatively unaffected suburbs reporting starting medication compared to 9.1% in affected suburbs. However, there was a significant association between starting medication and average income level, $\chi^2 (2, n=596)=10.10, p=.006; V=.13$, with higher medication commencement in lowest income (12.1%) compared to medium (8.6%) and high (3.5%) income areas.

A 2-factor MANCOVA with increase in alcohol, cigarette and recreational drug use as dependent measures revealed the significant covariates of gender, Pillai’s trace=.02; $F(3, 586)=4.30; p=.005; \eta^2=.02$, and age, Pillai’s trace=.07; $F(3, 586)=14.12; p<.001; \eta^2=.07$. Furthermore there was a significant multivariate main effect of average income, Pillai’s trace=.04; $F(6, 1174)=3.84; p=.001; \eta^2=.02$, but no significant main effect of earthquake effect or interaction. Income produced a significant main effect on increased cigarette, $F(2,588)=9.50; p<.001; \eta^2=.03$, and recreational drug use, $F(2,588)=4.19; p=.031; \eta^2=.01$. Respondents from low ($p=.021$) and medium ($p<.001$) income areas reported more increases in smoking than high income areas. Respondents from medium ($p=.014$) income areas also reported more increases in recreational drug use than the high income group. There was no significant main effect of income on alcohol use. Thus, although alcohol use demonstrated significantly greater increases than smoking ($p<.001$) or drug use ($p<.001$), these increases appeared relatively uniform across income areas (see table 6).

INSERT TABLE 6 ABOUT HERE
**Average income and earthquake effects on functioning**

A 2-factor MANCOVA with the 2 functional disruption scales (relationship and general disruptions) as dependent measures revealed the significant covariates of gender, Pillai’s trace=.02; $F(2, 584)=7.09; p=.001; \eta_p^2=.02$, and age, Pillai’s trace=.05; $F(2, 584)=16.85; p<.001; \eta_p^2=.05$. There were significant multivariate main effects of average income, Pillai’s trace=.09; $F(4, 1170)=13.02; p<.001; \eta_p^2=.04$, and earthquake effect, Pillai’s trace=.02; $F(3, 584)=73.08; p<.001; \eta_p^2=.02$, and a significant multivariate interaction, Pillai’s trace=.05; $F(4, 1170)=7.03; p<.001; \eta_p^2=.02$. Income produced a significant main effect on general functional disruption scores, $F(2,585)=25.70; p<.001; \eta_p^2=.08$, with respondents from low ($p<.001$) and high ($p<.001$) income areas reporting more disruption than medium income areas (see table 7). There was no significant main effect of income on relationship disruption scores.

The main effect for earthquake effect showed that participants living in the affected suburbs had significantly higher relationship disruption, $F(1,585)=18.21; p<.001; \eta_p^2=.03$ and general disruption, $F(1,585)=146.28; p<.001; \eta_p^2=.20$, than those living in relatively unaffected suburbs (see table 7). There was a significant interaction between average income and earthquake effect on relationship disruption, $F(2,585)=3.11; p=.045; \eta_p^2=.01$. Respondents from low income areas living in affected suburbs had significantly higher relationship disruption ($p<.05$) than respondents from low and medium income areas living in relatively unaffected suburbs. Respondents from the high income areas living in affected suburbs had significantly higher relationship disruption ($p<.05$) than respondents from low income, relatively unaffected suburbs. There was a significant interaction between average
income and earthquake effect on general disruption, \( F(2,585)=14.27; p<.001; \eta^2=.05. \) The highest general disruption mean scores were reported by the low income affected group and was significantly higher \((p<.05)\) than all the other 5 groups. The second highest mean score was the high income affected group which reported significantly higher mean scores \((p<.05)\) than the medium income affected group and all of the relatively unaffected groups (irrespective of income level). Finally the medium income affected group reported significantly higher mean scores \((p<.05)\) than the medium and low income relatively unaffected groups.

**Discussion**

The current study is one of the first to systematically assess the impact of average household income and level of physical damage on psychological distress in a community sample following a fatal earthquake. Those in the physically damaged (affected) suburbs were more likely to have moved house, lost utilities and accessed health/mental health and social services after the earthquake compared to those in relatively unaffected suburbs. Despite the considerable physical impact across the whole sample, within the affected suburbs, those in the high income area were more likely to have moved house after the earthquake (perhaps in part because they had the means to) and lost utilities. High income affected participants were more likely to access social services, while low income affected participants were more likely to access health and mental health services. Mental health problems were common in the total sample, with over a third reaching diagnostic cut-offs for acute stress disorder, anxiety and/or depression. Moreover, alcohol use increased across the whole sample,
potentially as a means of chemically self-regulating heightened stress. However, even though the high income suburbs reported higher levels of utility loss and moving from their homes as a result of the earthquake, mental health problems were more evident in low income areas. The low income areas reported higher anxiety symptoms, even when age, gender and social isolation were controlled for, and were more likely to reach diagnostic cut-offs for mild and moderate depression and anxiety. Perhaps on account of their higher psychological symptoms, those in low income areas were more likely to have started psychiatric medication post-earthquake, and at least compared to the high income group, reported an increase in cigarette use. The low income areas reported more daily functioning problems (e.g., work, household tasks, leisure activities) compared to the medium income areas.

Individuals in affected areas experienced more acute stress, depression and anxiety symptoms than those in relatively unaffected areas, and were more likely to reach diagnostic cut-offs for acute stress disorder, mild and moderate depression and moderate and severe anxiety. These same participants also experienced more problems in relationship and daily life functioning.

While neighborhood context and financial resources were associated with earthquake-related outcome, the combination of earthquake effect and average income level seemed less important to understanding outcome than each factor uniquely, as their interaction was only meaningful for depression and functional disruptions. Most evidently, those with less financial resources who were from the most affected neighborhoods, reported more mood-related problems and greater disruptions in relationship and daily life functioning. In short, these findings suggest that lower average income and level of physical damage have discrete and unique impacts on earthquake-related distress. Low average income leaves people
particularly prone to anxiety and depression, with increased exposure to physical
damage post-earthquake heightening mood difficulties further. Increased physical
exposure independently heightened anxiety and depression, but appeared to have a
unique impact on increasing posttraumatic stress symptoms. Heightened distress in
participants residing in areas most physically affected by the earthquake is consistent
with other studies (Carr et al., 1995).

Across the whole sample, the earthquakes continued to have a very significant
impact on mental health functioning 4-6 months after the fatal earthquake. Level of
acute stress disorder diagnosis across suburbs ranged from 30%-54%. For depression
and anxiety diagnosis, the range was 23%-72% and 27%-67%, respectively. These
rates are consistent with prior research conducted around 6 months post-earthquake
(e.g., Kuwabara et al., 2008). Thus, the psychological impact of earthquakes is not
limited to those highly affected by personal and neighborhood damage, or low
average household incomes. Rather earthquakes appear to have a more far-reaching
and chronic impact. However, even with the powerful predictors of age, gender and
social isolation accounted for, average household income and degree of neighborhood
damage continued to be salient indicators of poorer psychological outcome.

With reference to posttraumatic stress symptoms in the current study, residing
in areas severely affected by the earthquake, had a uniform impact on increasing all
four posttraumatic stress symptom markers (i.e., dissociation, intrusions, avoidance,
arousal). Diagnostic criteria for both acute stress and posttraumatic stress disorders
are based on exposure to traumatic events in which acute harm or possible death to
self or others occurs. Other studies have shown that posttraumatic stress symptoms
following earthquakes are associated with direct trauma exposure (Zhou et al., 2013).
Yet the current study reported increased posttraumatic stress symptoms in those
whose neighborhoods and houses experienced the greatest physical damage. It is unlikely that such people were disproportionately exposed to death, harm and destruction when the earthquake hit, as fatalities, building collapse, injuries and people being trapped, were for the most part isolated to the city centre, which draws people from across all suburbs. Thus there is something about living day-to-day with the physical ongoing aftermath of an earthquake that seems to be associated with posttraumatic stress symptoms, beyond any contribution from direct exposure. This may be due to 1) the insidious nature of ongoing stress in affected areas (Dorahy & Kannis-Dymand, 2012; Scott & Stradling, 1994), 2) the notion that living with distressing reminders in the context of ongoing disruption may maintain already elevated dissociative symptoms and inhibit effective conceptual processing of the whole series of events (Holmes, Brewin & Hennessy, 2004; Lyttle, Dorahy, Hanna & Huntjens, 2010), or 3) subjective cognitions and emotions (e.g., fear, shame, helplessness) maintained by the environmental cues. This study is one of many that suggest posttraumatic stress symptoms are not limited to events involving direct harm or threatened death (e.g., Alcorn, O'Donovan, Patrick, Creedy, & Devilly, 2010; Dorahy & Kannis-Dymand, 2012; Scott & Stradling, 1994).

Whilst being exposed post-earthquake to more neighborhood physical destruction appears to heighten psychological distress, in this study, unlike some others (e.g., Dorahy & Kannis-Dymand, 2012; Carr et al., 1995; Lima et al., 1989) distress was not simply related to increased exposure. Rather, average income influenced the severity of distress in those living in physically affected areas, especially for depression. The current research supports average income as an important psychosocial contributor, beyond the impact of known risk factors for poor mental health outcome following an earthquake, such as age, gender, social isolation
and exposure, found both here and in other studies (Armenian et al., 2002; Carr et al., 1997; Kiliç et al., 2006; Lima et al., 1989; Najarian et al., 2001; Sattler et al., 2006; Zhou et al., 2013). Residing in a lower income area was associated with greater anxiety and depression after the earthquakes, and more functional disruption in daily life. Potentially as a result of these increased difficulties, individuals in low income areas were more likely to commence medication use since the earthquake, and to self-soothe via increased cigarette consumption.

Following an earthquake, living in a low income area may contribute to greater psychological and functional difficulties due to mediating variables including lack of occupational, social and financial resources. Conservation of resources theory suggests that low income may be a chronic stressor, increasing psychological distress as a result of limited resource access and resource accumulation (Ennis, Hobfoll, & Schröder, 2000; Hobfoll, 2001, 2011). Acute resource loss (e.g., from an earthquake), in the context of chronic lower resources, punctuates the limited resources available to people in low income areas, heightening distress further (Ennis et al., 2000). Thus, personal and communal resource limitations are a central factor creating heightened distress in low income areas following earthquakes. The current findings suggest that income level should be considered a gross social indicator of outcome following earthquakes. Resources should be especially targeted towards low income areas in order to reduce the psychological impact and facilitate adjustment.

The only variables that responded to the interaction between income and earthquake effect were depression and relationship disruption. Both were elevated in those from low income areas who had more damage exposure. Previous work has shown a link between depression and relationship difficulties (e.g., Fincham, Beach, Harold & Osborne, 1997). What is unclear in the current study is the causal
relationship, and whether post-earthquake depressions lead to relationship problems, or whether the earthquake heightened relationship discord and daily functioning difficulties which contributed to lower mood. Both directional associations may be evident and dependent on variables such as gender (Fincham et al., 1997).

While average income level produced increases in anxiety and depression regardless of level of effect, it had no impact on acute stress symptoms. Only neighborhood damage exposure was related to posttraumatic stress symptoms. Thus, posttraumatic stress symptoms appeared sensitive to neighborhood physical exposure, but insensitive to income level. The finding that different psychosocial factors produce different outcomes has been reported previously (Carr et al., 1995). Ongoing exposure to earthquake aftermath appears to punctuate psychological functioning in a manner that produces the intrusive and avoidant symptoms characteristic of acute and posttraumatic stress. Socioeconomic variables, like average income seem to have a more eroding, rather than punctuating, impact on post-earthquake psychopathology.

The findings of this study were strengthened by a design that allowed methodological control of average household income and neighborhood exposure variables in a large community sample assessed face-to-face at a relatively short period after the earthquake. Known psychosocial variables effecting psychological outcomes were statistically controlled. Nonetheless, the study had limitations. Arguably the most pressing was the fact that two-thirds of households were either unoccupied when approached, or vacant. In all areas, but especially in the affected areas, many homes were uninhabitable after the earthquake. Previous occupants may have been more severely psychologically affected than those still residing in the neighborhood. Thus, an accurate representation of the psychological impact of those most affected may not have been achieved. The external validity of the study was also
impacted by low and medium income areas having a slightly higher ‘decline to participate’ rates (approx. 11%) than the high income area (3.5%), and slightly more ‘declines’ in the relatively unaffected area. Related to this, the methodology invited one adult participant in each household to be interviewed, and in some cases those who answered the door deferred to another member of the household to be interviewed. Anecdotally, this was sometimes a person most affected by the earthquake and, at other times, least affected. More stringent control of this feature, such as randomly inviting a specific person in each household (e.g., a male, a female, the oldest, the youngest, etc), may have produced more representative findings.

The current results suggest that in cities exposed to fatal earthquakes, distress is a widespread phenomenon not limited to average income or degree of physical damage experienced to area of residence. Yet, once other known distress-related variables are controlled, both income level and degree of ongoing neighborhood damage appear to make an independent, and in some cases joint, contribution to psychological distress and functional disruption. Thus, resource planning and distribution should initially extend across the whole region affected by the event (i.e., affected and relatively unaffected areas), with greater and ongoing resources further being targeted to areas more affected and those with less income. Given that income level significantly contributed to increased depression and anxiety symptoms, it should not be assumed that more affected areas have the highest psychosocial need. Lower income has its own significant impact on post-earthquake distress regardless of level of exposure to the aftermath of an earthquake.
