Just Accepted

“Just Accepted” manuscripts have been peer-reviewed and accepted for publication. They are posted online prior to technical editing, formatting for publication and author proofing. The American Chemical Society provides “Just Accepted” as a free service to the research community to expedite the dissemination of scientific material as soon as possible after acceptance. “Just Accepted” manuscripts appear in full in PDF format accompanied by an HTML abstract. “Just Accepted” manuscripts have been fully peer reviewed, but should not be considered the official version of record. They are accessible to all readers and citable by the Digital Object Identifier (DOI®). “Just Accepted” is an optional service offered to authors. Therefore, the “Just Accepted” Web site may not include all articles that will be published in the journal. After a manuscript is technically edited and formatted, it will be removed from the “Just Accepted” Web site and published as an ASAP article. Note that technical editing may introduce minor changes to the manuscript text and/or graphics which could affect content, and all legal disclaimers and ethical guidelines that apply to the journal pertain. ACS cannot be held responsible for errors or consequences arising from the use of information contained in these “Just Accepted” manuscripts.
The Importance of Acetonitrile in the Pharmaceutical Industry and Opportunities for its Recovery from Waste

Abstract

Acetonitrile is regarded as a key solvent in the pharmaceutical industry. However, the volatility in acetonitrile supply in recent years, coupled with its relatively poor environmental profile, has presented significant challenges to its use in manufacturing processes and laboratories. This study investigates the importance of acetonitrile in the pharmaceutical industry and critically examines several options for reducing the exposure of the industry to future supply problems whilst also improving its life cycle management. The physicochemical properties of acetonitrile were compared with other typical process solvents and the Conductor-like Screening Model (COSMO) surfaces and sigma profiles were used to help explain the favourable solvation behaviour of acetonitrile. Several options for the replacement or recovery and recycle of acetonitrile were critically examined in the contexts of environmental, technical and economic feasibility. Azeotropic distillation was found to be the most likely approach to recovering acetonitrile from aqueous waste streams. Several potential breaking agents were assessed against a range of selection rules based on residue curve maps, determined using the Universal Functional Activity Coefficient (UNIFAC) method, and potential processing issues. A range of ionic liquids were screened via the predictive Conductor-like Screening Model for Realistic Solvation (COSMO-RS) approach and several promising candidates were identified. Experimental vapour-liquid equilibria studies were carried out, confirming the feasibility of ionic liquid-enhanced azeotropic distillation as a novel approach to acetonitrile recovery.
1 Introduction

Acetonitrile (MeCN) is a core solvent in the chemical industries, particularly the pharmaceutical industry, where the global demand accounts for over 70% of the total market. The high popularity of MeCN is due to its excellent solvation ability with respect to a wide range of polar and non-polar solutes, and favourable properties such as low freezing/boiling points, low viscosity and relatively low toxicity. Several key properties of MeCN are shown in Table 1 and compared with similar solvents. Currently the pharmaceutical and fine chemical industry has two major uses of MeCN: (a) laboratory use, particularly as a mobile phase in liquid chromatography analytical techniques, and (b) as an industrial process solvent, for example, in the manufacturing of antibiotics. Due to the need for very high purity solvents in analytical techniques such as high performance liquid chromatography (HPLC), laboratories tend to use “Analar” grade MeCN, whilst industrial applications favour “technical grade” MeCN due its lower cost. In both cases, the solvent is very highly refined in terms of purity, typically >99.9% for Analar and >99.5% for technical grade.

The vast majority of MeCN is manufactured as a by-product of acrylonitrile production. During the period 2008 to 2009, issues associated with the MeCN supply position were raised as a major concern within the pharmaceutical industry. With a limited demand for acrylonitrile as a result of the world economic downturn, the supply of MeCN was reduced significantly, probably by at least 50% in 2008, although figures are difficult to determine accurately. There was a further shortfall in 2009 and once again it was difficult to predict where the supply would bottom out. During the shortfall period, supply costs were typically increased, peaking at six times the normal cost. Such volatility in price caused interruptions in the normal supply chain as a number of operators reviewed their positioning in the market. This had a major impact on the pharmaceutical industry, with drastic measures, such as stringent stock control, prioritisation of use and sourcing solvent for intermediate suppliers, for example, being taken to mitigate their supply problems in the short term. All new sources of MeCN on the market had to undergo user requirement trials to ensure no detrimental impact on the process or product.

In addition to supply volatility, MeCN presents further challenges to its industrial use. A general solvent selection review recently concluded that there are major issues associated with MeCN use in the pharmaceutical industry such as difficulties in dealing with waste...
MeCN and its poor scoring with regard to life cycle management. Therefore, the recent volatility in supply of MeCN combined with environmental challenges presents the industry with a major incentive to develop new, more sustainable approaches to MeCN use. Herein is presented a review of the options for MeCN conservation in use, including a technical assessment based on experimental and predictive analysis.

2 Why is MeCN such a good solvent?

As alluded to previously, MeCN is regarded as a good solvent because of its ability to dissolve a wide variety of fine chemical and pharmaceutical ingredients, with an acceptable environmental profile, even though a sustainable supply cannot be guaranteed. It has, therefore, tended to be a favoured solvent by process chemists, although, for some manufacturing processes, its relatively high cost would be regarded as contributing unduly to the cost of production. MeCN is also relatively inert, due to the strong C-C bond which can only be hydrolysed under extreme conditions, making it an excellent reaction solvent.

The Conductor-like Screening Model (COSMO) σ-profile\(^1\) is a useful qualitative tool in explaining the solvent properties of molecules, as shown in Figure 1 for four different solvents: MeCN, water, NMP and hexane. The σ-profile is a statistical representation of the surface charge distribution on a given molecule as determined from the quantum-based COSMO calculation\(^1\) and it is possible to use the profiles to interpret the likelihood of a molecule to form strong Coulomb interactions with a wide variety of compounds. This is illustrated via comparison with a strong dielectric, such as water, and a non-polar molecule such as hexane. The abscissa of the profile describes the electron density of the molecular surface with positive values indicating a high electron density and electronegativity whilst negative values indicate low electron density, or electropositive regions. The ordinate describes the relative areas of molecular surface possessing such electron densities. Water is represented by the uppermost surface plot followed by MeCN in the centre and finally hexane as the lowermost plot. Notice the narrow profile of hexane, which is centred on the 0.00 σ value, illustrating the non-polar nature of the compound. The σ-profile of hexane ranges from -0.5 to +0.6 e/A\(^2\), with a maximum at -0.1 e/A\(^2\) arising from the hydrogens, and a shoulder at about +0.2 e/A\(^2\) arising from the exposed surfaces of carbon atoms. The σ-profiles of other alkanes look very similar, and mainly differ in height due to the differences in the total surface area. Thus the moderate electron density of the functional groups can be recognised in the sigma surface plot via green colour coding. Similarly, if one considers the profile for
water, the two hydrogen atoms can be identified by the peak at around -0.015 e/Å², whilst the electronegative oxygen is highlighted at around +0.015 e/Å². In the colour coding of the surfaces these regions can be recognized as deep blue and deep red respectively. The symmetry of the water profile is very important as this implies partner contact surfaces for each area on adjacent water molecules. Symmetry indicates high molecular affinity within a pure compound and hence water “likes itself” very much, resulting in a high boiling point. Qualitatively, the $\sigma$-profile for MeCN lies amidst the two extremes mentioned. The electronegative nitrogen atom is illustrated by the peak around +0.01 e/Å² whilst the electropositive hydrogen atoms are shown via the peaks located around 0.0075 e/Å². Furthermore, the peak at approximately 0.0025 e/Å² highlights the central non-polar carbon atom of the molecule. Once again, these regions can be identified on the sigma surface plot as deep red, light blue and green respectively. Neglecting the obvious steric differences, both water and MeCN possess similar charge silhouettes. The possession of such a charge distribution results in balance of both moderate and more pronounced polarities highlighting the versatility of the compound to dissolve a range of polar and non-polar media. From Table 1, the solvent with the physicochemical properties most similar to MeCN, such as dielectric, log $P$ and miscibility, is N-methyl-2-pyrrolidone (NMP). The downside of NMP is that it has a relatively high boiling point and is difficult to recover from aqueous waste, requiring abatement largely by incineration. NMP is also a solvent whose hazard rating is under close review and tending to require more precautions to be taken as more is understood about its systemic mode of action.
3 Review of the options for dealing with the MeCN supply problem

Given the challenges faced by the pharmaceutical industry as a result of MeCN supply problems in recent years, several options exist for minimising the impact of the volatile market supply. These have been drawn up within the context of the hierarchy of waste minimisation as given in EU Directive 2008/98/EC, and are summarised in Table 2. A number of hybrid options associated with the main options are also shown in the table. MeCN sent for recycle is a complex mixture of solvents and other agents. Technically, the best short term solution to the supply shortage of MeCN is to control and reduce usage and to examine if MeCN can be recycled for use in other manufacturing sectors to free up use of ‘virgin’ MeCN for the pharmaceutical industry.

Recycle and reuse is by far the most popular activity for managing MeCN supply and demand. The method that has reached commercial potential is azeotropic distillation although a number of other more novel techniques such as membrane filtration and pervaporation have had some limited success.

A multi-stage column will have the capability to recover MeCN using a breaking agent. However, following the guidelines issued by the International Conference on Harmonisation of Technical Requirements for Registration of Pharmaceuticals for Human Use (ICH), solvents classified as ICH Class 3 (low toxicity potential) or, perhaps, Class 2 (solvents to be limited) would be preferred. A number of current good manufacturing practice (cGMP) hurdles need to be overcome to reuse MeCN. From a sustainability point of view, the most powerful corporate social responsibility approach would be to review previous activity in MeCN supply and reuse. The waste hierarchy can be applied in order of preference: prevent, minimise, reuse, recycle, energy recovery and disposal to the MeCN – supply and use. Prevention is almost impossible due to the physical property characteristics of MeCN for analytical and process use.

In terms of minimising MeCN consumption within analytical science, focus has been centred on the development of novel HPLC methods which avoid MeCN use entirely. Alcohols such as methanol and ethanol have been proposed for a number of limited systems. In this manner the pharmaceutical industry can also moderate its laboratory use of MeCN. However, the versatility of MeCN is impossible to reproduce with other such solvents over a wide range of systems.
4 Relevant previous research on MeCN replacement or recovery

In the past two decades, significant efforts have been taken to investigate and develop technologies for dealing with the sustainability issues associated with MeCN use in the pharmaceutical industry. The research and technological developments can be sub-categorised into four main areas: solvent substitution; recycle using azeotropic distillation; recycle using physical separations; novel manufacturing processes. For convenience, these have been summarized in Table 3, with further explanation given under the sub-headings below. A further section on more recent developments using predictive approaches to identifying possible approaches to MeCN recovery is also included.

4.1 Solvent substitution

The impact of the MeCN shortage led several researchers to investigate the replacement of MeCN in pharmaceutical HPLC applications with readily available and low cost alternatives such as methanol or ethanol. Whilst some success has been reported as described earlier, the studies are limited to a few isolated HPLC applications and the authors concede that, when available, MeCN remains the preferred mobile phase in such cases. Furthermore, due to their relatively high reactivities, methanol and ethanol would be inappropriate to replace MeCN in most applications as a reaction solvent.

There is a general movement within the SHE community to remove solvents that have specific issues; for example, in recent times, industrial use of dichloromethane has been significantly restricted in Europe due to safety concerns. Within industry, therefore, the view should be to largely remove MeCN from process development as early as possible to avoid any legacy issues that may occur with supply or other issues at later stages. From the point of view of the process chemist, however, this approach is seldom adopted because MeCN is such a useful reaction solvent for the reasons outlined earlier.

4.2 Azeotropic distillation for MeCN recovery

Several researchers have investigated the use of extractive and azeotropic distillation to achieve the recovery of MeCN from aqueous waste. Acosta-Esquijarosa et al. proposed a combined process of butyl-acetate solvent extraction followed by distillation. Using this technique the authors claimed an 83.4% recovery of MeCN with a purity of 98.51%. Gomez et al. proposed novel methods using hybrid pervaporation-distillation units for MeCN recovery. This work did not cover the impact of the potential decomposition of butyl acetate.
to form butanol and acetic acid. From Table 4a, it is possible to identify a number of azeotropes that will influence the quality of the separation of MeCN for butyl acetate e.g. BuOH/BuOAc, BuOH/HOAc and various other azeotropes if small amounts of water are formed. The azeotrope may also be broken via the use of an entrainer, i.e. an additive which shifts the thermodynamic equilibrium in such a way that the azeotrope is eliminated. Details on the processes and feasibility of such operations have been offered by Bernot et al.\textsuperscript{21} and Dussel and Sticklmair,\textsuperscript{22} whilst a complete overview of entrainer selection techniques for homogeneous azeotropic batch distillation has been given by Rodriguez-Donis et al.\textsuperscript{23} The same group also investigated heterogeneous azeotropic distillation by using an acrylonitrile entrainer within aqueous MeCN batches yielding a recovery close to 80%\textsuperscript{24} However, due to the use of acrylonitrile, the co-product of MeCN, this technique has little potential impact on MeCN shortage. To address this problem, the same researchers screened several alternative entrainers by simulating, via the Universal Functional Activity Coefficient (UNI FAC) method, the separation of MeCN-water systems using heterogeneous batch distillation,\textsuperscript{25} identifying two potential entrainers, hexylamine and butyl acetate, from various amines, alcohols, esters, ketones and aromatics.

“Salting out” involves the preferential solvation of salt ions in water at the expense of the tertiary component thus forcing the formation of biphasic systems. Ligette et al.\textsuperscript{26} illustrated that MeCN-water phase separation can be induced at 25 °C with addition of NaCl. Building upon this, Gu and Shih\textsuperscript{27} obtained a 60% recovery of MeCN from an aqueous HPLC effluent stream using a combination of phosphate salts and cooling to 4 °C. Zhang et al\textsuperscript{28} examined the extraction of platinum group metals (PGM) from aqueous solutions using NaCl-MeCN-diisopentyl sulphide to form a three-liquid-phase-system. The authors present the aforementioned as an optimum system for PGM recovery furthermore highlighting the adept ability of salts to induce phase separation in aqueous MeCN systems. However, one inconvenience when using this technique is the need to use a pH buffering agent to protect sensitive components such as enzymes, for example. The use of salts may also be problematic in that they, under certain conditions, may precipitate out of solution, leading to fouling problems in process equipment. Furthermore, the prospect of unwanted reactions with impurities and complications due to corrosion may negate the use of such additives. Such problems may be overcome via the use of dissimilar mass separating agents such as sugars. “Sugaring out” is another innovative technique which operates in a similar fashion to salting out however the additive here is usually a monomeric sugar or disaccharide. In such systems
the sugars preferentially hydrogen bond to the water molecules forcing the MeCN into a distinct phase. The concept was proven by Wang et al\textsuperscript{29} with glucose, fructose, xylose, arabinose, sucrose, and maltose; however, it was unsuccessful when using polysaccharides. When considering the partition of syringic acid and furfural the concentration of said components in the organic phase increased with sugar concentration. Glucose was the most effective of the sugars studied. Dhamole et al.\textsuperscript{30} investigated the effect of glucose concentration, temperature and initial amount of MeCN on the sugaring out process to recover proteins from aqueous solutions. As a result, an 83\% (v/v) MeCN enrichment of the organic phase was achieved at 60°C and 0.012 mole fraction glucose. Sugars, however, carry the risk of microbial growth, which could present significant issues in pharmaceutical processing. Furthermore, like salts, sugars may precipitate from solution during processing and lead to fouling issues.

Traditional laboratory methods of subzero cooling (to approx. -20 °C) to crystallise out water for removal by filtration are associated with high operating costs. Hence, such techniques have arisen as a direct result of MeCN supply and demand in an aid to keep costs down by recycling the solvent internally in a cost effective manner. That being said, the industrial applications of such techniques are highly attractive.

Ionic liquids have attracted significant attention recently as potential azeotrope breakers for a wide range of systems. They are essentially salts which are liquid at or near room temperature and are typically made up of organic cations and inorganic anions, thereby combining some of the properties of organic entrainers with those of inorganic salts. The advantages of ionic liquids include their negligible vapour pressures,\textsuperscript{31} making their separation and recycle of relatively straightforward, and the fact that their physical and thermodynamic properties can be tuned by varying the cation-anion combination and hydrocarbon chain lengths. It has been estimated that, theoretically, there are over 10\textsuperscript{6} possible ionic liquids, each with different physicochemical properties.\textsuperscript{32} Therefore, with the emergence of appropriate computational screening technologies, the potential exists to optimally design ionic liquids as azeotrope breakers for a given separations problem. Whilst the lack of extensive toxicity data for novel ionic liquids is a major barrier to their direct use in pharmaceutical processing in the short to medium term, they have potential to be used as azeotrope breakers where the MeCN is to be recycled externally to non-cGMP processes. A detailed review of the application of ionic liquids as azeotrope breakers has been recently published by Pereiro et al.\textsuperscript{33} Here the authors cite references for the use of ionic liquids as
azeotrope breakers in a range of water + alcohol, water + THF, alcohol + ester, alcohol + ketone, alcohol + hydrocarbon, alcohol + halogen and aromatic + aliphatic systems, whilst also offering a comparison with published data regarding more conventional entrainers. Contrast is also made between azeotropic breaking and extractive distillation where appropriate. However, there is no published work on the use of ionic liquids for azeotropic distillation of water + nitrile systems, which is a clearly an area needing urgent attention.

4.3 Physical separation techniques for MeCN recycle

As well as azeotropic distillation, other approaches have been reported for the separation of MeCN from water. For example, Pfenning and Woermann\textsuperscript{34} describe hyperfiltration experiments using phenolsulfonic acid (PSA) membranes for the separation of MeCN from water. More recent work on the use of commercial membrane based techniques for solvent dehydration has been reviewed by Hoof et al.\textsuperscript{35} Whilst some promising results have been achieved, the major technological challenge in this area is producing membranes of sufficient robustness and chemical stability for commercial use.

Khayet\textsuperscript{36} used the pervaporation process to successfully separate binary solutions of acetone-water, MeCN-water and ethanol-water as well as multicomponent systems using Sulzer Pervap\textsuperscript{®} 4060 membranes. More recently, Mandal\textsuperscript{37} examined the separation of MeCN-water systems using Pervap\textsuperscript{®} 2202 and nanocomposite PVA-iron oxide membranes delivering up to 99% (wt) water in the permeate. Both papers suggest that this is an efficient and cost effective separation technique. However, these methods have yet to achieve commercial viability.

4.4 Novel manufacturing processes

In addition to elimination of MeCN use or separation and recycle, many industrial and academic researchers have tried to bypass the MeCN supply chain problem by introducing a direct manufacturing process for MeCN. There are a number of commercial routes to synthesize MeCN and recently, Bayer\textsuperscript{38} has developed a process for the manufacture of isocratic grade MeCN in a pilot plant with a capacity of around 4m\textsuperscript{3} per week. NITRALZ\textsuperscript{®39} is another process for the direct synthesis where after an ammoxidation reaction, pressure swing distillation is utilized to manufacture up to 99.9% HPLC grade MeCN. Moreover several academic papers have been published highlighting novel manufacturing techniques. Zhang et al.\textsuperscript{40} examined the amination of ethanol to MeCN over a Ni-doped Co/γ-Al\textsubscript{2}O\textsubscript{3}
Catalyst with MeCN being obtained with a yield >82% under the optimum reaction conditions (drying at 120°C and calcining at 550°C) for 720 h. Furthermore in 2011 the authors published the intrinsic kinetics of the process in a fixed bed reactor for the temperature range 613-643 K. A concise overview of previous developments in MeCN process development was also covered by the authors and shall not be reiterated here. However, one important area considers the use of ethane as a feedstock. Li and Armor have published a number of papers describing the ammoxidation of ethane to MeCN (Equation 1) over a range of zeolite catalysts indicating that Co-ZSM-5, Co-beta and Co-Nu-87 to be superior with ethane conversions of 38.2%, 35.3% and 26.7% respectively.

\[ \text{C}_2\text{H}_6 + \text{NH}_3 + 1.5\text{O}_2 \rightarrow \text{C}_2\text{H}_3\text{N} + 3\text{H}_2\text{O} \] (1)

In contrast, Rojas et al. describe the ammoxidation of ethane over a niobium modified NiO catalyst with a 19% MeCN yield. With further catalyst development and improvements in reaction yield, coupled with the increasing volatility in acetonitrile supply via the existing route, this novel approach has the potential to gain industrial importance.

### 4.5 Predictive engineering science approach

The use of predictive tools in pharmaceutical process development is becoming increasingly important, particularly in the preliminary screening of solvent systems, to reduce costly and time-consuming experimental screening studies. Well established group contribution approaches such as UNIFAC have been found to work reasonably well when dealing with species containing the more common functional groups. However, where more “exotic” species are involved, as is often the case in pharmaceutical processes or in systems involving ionic liquids, UNIFAC cannot be applied due to the lack of group interaction parameters for many functional groups. Quantum-based \textit{a priori} approaches to thermodynamic prediction, such as COSMO-RS, have received significant attention in recent years, due to their wide ranging applicability without the need for experimental data or group interaction parameters. Some work has been carried out recently to investigate the use of COSMO-RS for predicting the solubilities of pharmaceutical compounds and ionic liquid-based systems. However, despite the recent interest in COSMO-based approach for predicting phase equilibria, there has been very little attention in the literature given to its use in MeCN-containing systems.
5 Case study on the recovery of MeCN from the MeCN–water–toluene system

MeCN-water-toluene is a ternary system that is typically encountered in the pharmaceutical industry and can be found in several registered processes. Initially a reaction takes place with MeCN as the reaction solvent. Separation of the organic and inorganic species is achieved by the addition of water to extract the inorganics. Since acetonitrile is fully miscible with water, it is then necessary to back extract the acetonitrile, and any other organics, into toluene. The ternary liquid-liquid equilibria of the MeCN-water-toluene system at 20 °C is shown in Figure 2, illustrating typical Type I phase behaviour. The figure also shows good agreement between data obtained in this experimental study, COSMO-RS prediction and previously reported data \(^{50}\) for the ternary system.

5.1 Distillation of the MeCN-water-toluene system

Due to the formation of several azeotropes, this is a complex system from a separations perspective. The MeCN/water/toluene system has four azeotropes (see Table 4a and 4b) as follows:

(i) MeCN and water (homogeneous)
(ii) water and toluene (heterogeneous)
(iii) MeCN and toluene (homogeneous)
(iv) MeCN/water/toluene (heterogeneous)

MeCN and water form a homogeneous azeotrope when distilled. Therefore, in principle, if a breaking agent is introduced, it would be possible to continue distilling and condensing until a relatively pure MeCN stream is achieved. However, this separation will also be influenced by the presence of other impurities in the feed stream. Reduction of water to extremely low levels will probably require an extra dehydration step which would be a slow and time consuming distillation. The ternary azeotrope has the lowest boiling point at atmospheric pressure and, therefore, will come off first in a binary distillation. A number of other solvents that might be present in waste MeCN are shown in Tables 4a and 4b.

5.2 Selection and use of azeotropic breaking agents

The review of options for MeCN recovery from aqueous waste identified the use of azeotropic distillation as the approach with the greatest potential, in the short to medium
term, to address problems in MeCN supply. To further examine the feasibility of this
approach within the context of pharmaceutical processing, the following ICH Class 3
solvents were considered as breaking agents: acids (acetic and formic acid), ketones (acetone,
methyl ethyl ketone, methyl isobutyl ketone), ethers (MTBE, diethyl ether), alcohols (1-
propanol, 1-pentanol, 2-methyl-1-propanol, n-butanol, ethanol, 2-butanol, 2-propanol and 3-
methyl-1-butanol), esters (methyl acetate, isopropyl acetate, n-butyl acetate, isobutyl acetate,
ethyl acetate, ethyl formate, n-propyl acetate) and others (DMSO, n-pentane, n-heptane).
Since batch distillation is the most commonly used approach to separation and purification in
the pharmaceutical industry, these solvents were screened according to the practical entrainer
selection rules and guidelines for heteroazeotropic batch distillation described by Skouras et
al.51 and summarised below:

- Entrainer selection rule 1: “The entrainer should form a heteroazeotrope with one of
  the original components and/or a ternary heteroazeotrope.”
- Entrainer selection rule 2: “The vertex of the original component to be obtained in the
  still at steady-state should be connected with the steady-state reflux point of the
  entrainer-rich phase, with a distillation line in the direction of increasing temperature
  from the top of the column to the bottom.”
- Guideline 1: “The entrainer must not lead to the formation of maximum azeotropes
  with any of the original components.”
- Guideline 2: The entrainer should preferably not lead to the formation of a ternary
  saddle homoazeotrope.”

Two examples of the residue curve maps (RCM) generated for the (a) MeCN-water-MTBE
system and (b) MeCN-water-N-propyl acetate system are shown in Figure 3 to illustrate the
application of the entrainer selection rules. The first RCM illustrates that MTBE passes each
of the entrainer rules and guidelines and, therefore, has potential for the separation of MeCN
and water. On the other hand, N-propyl acetate fails the second entrainer selection rule and is
not suitable as an entrainer in this system. For brevity, the detailed results of the entrainer
screening for several other ICH Class 2 and Class 3 solvents can be found in the supporting
information. Three solvents emerged from the entrainer screening study as potential
candidates: MTBE, n-pentane and ethyl formate. Tables 4a and 4b provide information on
the binary and ternary azeotropes for several mixtures involving water and/or MeCN to
illustrate how a tactical separation of MeCN could be planned for a mixed solvent system
with MTBE and the previously investigated BuOAc. Due to the likely harsh environment in
a multi-compound solvent distillation it is probably best to avoid esters due to hydrolysis. In
the case of ethyl formate, under the wrong conditions carbon monoxide and hydrogen may be
formed, presenting a significant safety issue. N-pentane has not been considered due to its
relatively high volatility and special conditions needed to contain it.

5.3 Ionic liquids as alternative azeotropic breaking agents

In the review of MeCN recovery options above, the use of ionic liquids as azeotropic
breaking agents was identified as a previously unexplored route with significant potential. In
this work, a range of 51 ionic liquids were initially screened, using the predictive COSMO-
RS approach, for their ability to break the MeCN-water azeotrope. These ionic liquids were
chosen as they are reasonably well characterised and can be purchased from major ionic
liquid suppliers. The structures of these ionic liquids are shown in Chart 1. Initially, the
vapour-liquid equilibria of the MeCN-water system were simulated at atmospheric pressure
using the COSMO-RS method. In order to check the validity of the simulations, a series of
VLE experiments were carried out using the apparatus shown in Figure 4, with the x-y plot
for the experimental and predicted VLE shown in Figure 5. There is good agreement between
the COSMO-RS model and the experimentally determined VLE values for the MeCN-water
system, including the accurate detection of the azeotrope point at approximately 0.7 mole
fraction MeCN and 351 K. On the basis of this validation, a series of simulations were
performed on the VLE of the MeCN-water system with varying amounts of 51 different ionic
liquids added. A summary of the results obtained from the predictive screening calculations is
shown in Table 5. It is observed that the ability to break the MeCN-water azeotrope is
strongly dependent on the anion of the ionic liquid. For example, with the series of [C$_4$mim]$^+$
based ionic liquids, the following general anionic trend is observed (from most effective to
least effective):

[CI$^-$] $\approx$ [CH$_3$COO$^-$] $>$ [CF$_3$COO$^-$] $>$ [Br$^-$] $\approx$ [Tos$^-]$ $>$ [NO$_3$] $>$ [MeSO$_4$]$^-$ $\approx$ [EtSO$_4$]$^-$ $>$ [OTf]$^-$ $>$
[BF$_4^-$] $>$ [NTf$_2$]$^-$

The observed order coincides with the inverse of the trend found in ionic liquid
hydrophobicity, which studies$^{52}$ have shown increases from [NTf$_2$]$^-$ $>$ [BF$_4^-$] $>$ [I$^-$] $>$ [Cl$^-$].
Furthermore, the decrease in azeotrope breaking ability with increasing cation length for
ionic liquids based on the [BF$_4^-$] anion mirrors the decrease in hydrophilicity with increasing
chain length.$^{53}$ This indicates that the affinity of the ionic liquid towards water plays a
crucial role in its ability to break the MeCN-water azeotrope. Comparison of the sigma surfaces for some of the anions investigated, shown in Figure 6, suggests that anions which contain areas of high electron density tend to be more suitable for breaking the azeotrope of the MeCN-water system. In addition to the ionic liquids screened, COSMO-RS was used to predict the azeotrope breaking ability of two common salts, [NH₄][Cl] and [NH₄][CH₃COO]. The results coincide with the behaviour of ionic liquids containing the same anions however these ammonium salts can easily decompose to form HCl, ammonia or acetic acid, leading to corrosion issues.

Whilst the effect of an ionic liquid on the VLE of the MeCN-water system is clearly the primary factor in determining the optimal breaking agent, cost is also a key consideration. The costs of ionic liquids vary widely, by several orders of magnitude, mainly due to their relative novelty and the lack of large scale processes for their manufacture. As an indication, relative costs based on typical laboratory prices of the various ionic liquids are also shown on Table 5, although caution should be exercised since the relative bulk manufacturing costs of the ionic liquids may differ significantly from the relative laboratory prices. Other potential issues which may affect the suitability of specific ionic liquids for use as entrainers, such as high viscosity, corrosive nature or chemical instability, are also detailed in Table 5.

In order to provide some validation to the predictive screening results, three ionic liquids were chosen for experimental investigation. [P₆,₆,₆,₁₄]Cl and [C₈mim]Cl were chosen due to their promising screening results, relatively low cost and ease of availability. To provide a validation at the other end of the scale, [N₂,₂,₂,₈][NTf₂] was chosen as an ionic liquid which was not able to break the MeCN-water azeotrope. The VLE results are shown in Figure 5, Figure 7 and Figure 8 respectively. Due to the non-volatile nature of ionic liquids, the VLE can be represented using a typical binary x-y plot for MeCN and water, rather than using the residue curve maps shown previously. In all cases, the results suggest that COSMO-RS is qualitatively useful in predicting the VLE data for the IL-MeCN-water systems. In the case of [C₈mim]Cl, the experimental data closely maps the VLE predictions. For [N₂,₂,₂,₈][NTf₂], only one equilibrium point was experimentally determined, at a liquid phase composition of 0.9 mole fraction of MeCN, which illustrates that the azeotrope is not broken in the presence of the ionic liquid, thus corroborating the predictive screening results.
Table 6 summaries the previous discussion by identifying the leading options for the recovery of MeCN from the MeCN-water-toluene system. For recovery to take place at a manufacturing site then the best use of multi-purpose plant is required. To this end, maximising the relative volatility and simplicity of equipment in a cGMP environment, minimising the cost of breaking agent and guaranteeing process robustness will lead to the best solution. From Table 6, the best external solution is multistage distillation with or without a breaking agent whilst internally the better solution may be to use an ionic liquid in conventional batch processing equipment.

6 Conclusions

This study has highlighted the importance of MeCN in the pharmaceutical industry and illustrated the need for implementation of recovery and recycle steps to improve its environmental profile and reduce exposure to supply volatility. It has been demonstrated that it is possible and feasible to recover and recycle MeCN from aqueous waste streams and ensure that the use of this process solvent is sustainable from a corporate social responsibility viewpoint. Several Class 3 solvents have been identified as potential entrainers in the distillation of MeCN-water mixtures. A number of recommendations have been made that would be helpful to toll convertors or commercial manufacturing organisations (CMO). It is unlikely that pharmaceutical grade MeCN can be manufactured and tactically recycled MeCN should be used in industries other than the pharmaceutical industry. Moreover, it has been demonstrated that the predictive science approach to the opportunities presented by MeCN sustainability allows novel technologies that are under development to be assessed quickly for viability and commercial success. In this way, the potential of ionic liquids as “designer” entrainers to enable the recovery and recycle of MeCN has been illustrated. The need for further investigation into the relevant safety, environmental and processing implications of ionic liquids in pharmaceutical processes to establish their potential utility in the medium-to-long term has been highlighted. Several alternative routes to manufacturing MeCN have also been highlighted and this approach merits further investigation to tackle the current supply issues associated with producing MeCN as a side product.

7 Experimental and computational methodology

MeCN and toluene used in the current study were obtained from Sigma Aldrich with purity in excess of 98%. [P\text{6,6,6,14}][\text{Cl}] was provided by Cytec and used as received. [C\text{6}\text{mim}][\text{Cl}] and
[C₈mim][Cl] were synthesised within QUILL by alkylation of 1-methylimidazole with the appropriate alkyl chloride according to previously reported procedures.⁵⁴ [N₂,₂,₂,₈][NTf₂] was synthesised within QUILL by the analogous reaction of triethyl amine with octyl iodide followed by the metathesis reaction with lithium bis(trifluoromethane)sulfonimide according to previously reported procedures.⁵⁴

VLE experiments were carried out to verify predicted results using the apparatus in Figure 4. This experimental set-up was initially validated by measuring VLE for the MeCN/water system and comparing with data available in the literature⁵⁵ as shown in Figure 5. Furthermore, to validate the experimental set-up for ionic liquid-containing systems, the VLE of the ethanol/water/[C₆mim][Cl] system was measured and compared with literature data. These results are shown in the supporting information. To obtain each point on the equilibrium curve, 50 ml of MeCN/water binary mixture with a known composition was weighed out using a Denver SI-234 balance and added to the VLE apparatus along with a stirrer bar. The flask was then placed in a heating block and fitted with a thermocouple and condenser. A 5 ml sample vial was fitted to the reflux tap to collect the condensed phase while the liquid phase was collected using a 5 ml syringe. The system was then insulated and heated to boiling point and allowed to reflux for 15 minutes insuring equilibrium was reached. After 15 minutes the temperature was recorded and 2 ml samples were taken from both the liquid and condensed phases and allowed to cool. The content of the top and bottom phases were analysed by NMR using a Bruker 300 MHz spectrometer. A small amount from each sample collected was added to NMR tubes along with a deuterated DMSO probe and submitted for proton analysis. The composition of each sample was obtained by quantitative analysis of the integrated NMR spectra. The quantitative accuracy of NMR for the MeCN/water/IL system was verified by analysing a range of ternary mixtures of known composition and the uncertainty was estimated to be ±5%.

Residue curve maps were generated using UNIFAC and UNIQUAC thermodynamic packages within Aspen Plus v. 7.2. COSMO calculations were performed on each individual ion or molecule using the TURBOMOLE⁵⁶ quantum chemistry package. Computations were carried out on the density functional theory (DFT) level, using the BP functional⁵⁷,⁵⁸ with a triple-valence polarised basis set (TZVP).⁵⁹ Where applicable, optimised radii⁶⁰ were used in the COSMO calculation (H=1.30, C=2.00, N=1.83, O=1.72, F=1.72, S=2.16, Cl=2.05, Br=2.16, I=2.32); otherwise, 1.17xvdW radii were used. COSMO-RS thermodynamic predictions of VLE were generated using COSMOTHERM software.

Nomenclature
MeCN – Acetonitrile
BuOH – butanol
BuOAc – butyl acetate
cGMP – current good manufacturing practice
COSMO-RS – Conductor-Like Screening Method for Realistic Solvation
DCM - dichloromethane
DMF – dimethyl formamide
DMSO – dimethyl sulfoxide
Immisc. - Immiscible
HOAc – acetic acid
MeOH – methanol
Misc. - Miscible
MTBE – methyl tertiary butyl ether

\( n \) is the known number of protons contained within the functional group
NMP – N-methyl pyrrolidinone
SHE – Safety, Health and Environment
THF – tetrahydrofuran
UNIFAC – Universal Functional Activity Coefficient
UNIQUAC – Universal Quasi-Chemical

Acknowledgements
The help and expertise of Bjorn Herschend (AZ) and William Mackintosh (AZ) is recognised in making this paper possible. The authors would also like to thank Cytec Industries and QUILL for providing the ionic liquids used in this study and DELNI for financial support.

Supporting Information
Detailed results for entrainer screening of Class 2 and Class 3 solvents can be found in the supporting information spreadsheet. Also included are the experimental results for the water/ethanol/[C₆mim][Cl] system used to validate the VLE apparatus for systems containing ionic liquids. This information is available free of charge via the Internet at http://pubs.acs.org/.

</table>

Potential to hydrolyse means that the solution can react with water to produce hydrolysis products. Does not break azeotrope indicates that the solution does not form an azeotrope with water.

<td>1</td>
<td>Easy at toll convertor</td>
<td>Ideally requires an excess of MeCN and &gt; 20 theoretical plates.</td>
</tr>
<tr>
<td>BuOAc</td>
<td>Low</td>
<td>Extraction followed by batch distillation</td>
<td>4.1*</td>
<td>Easy</td>
<td>Yes – conventional processing with a number of vessels used. Stability of acetate may be an issue.</td>
</tr>
<tr>
<td>NaCl</td>
<td>Low</td>
<td>Separation followed by batch distillation</td>
<td>8.9</td>
<td>Easy</td>
<td>No - requires large quantities of salt and corrosion may be an issue.</td>
</tr>
<tr>
<td>Glucose</td>
<td>Medium</td>
<td>Separation followed by batch distillation</td>
<td>1.7</td>
<td>Medium</td>
<td>No - microbial growth may be an issue.</td>
</tr>
<tr>
<td>[C₈mim][CH₃COO]</td>
<td>High</td>
<td>Simple batch distillation</td>
<td>9.9</td>
<td>Availability of ionic liquid may be an issue in the short term</td>
<td>Yes - after development and may be possible to include ionic liquid in reaction phase.</td>
</tr>
<tr>
<td>[C₈mim]Cl</td>
<td>High</td>
<td>Simple batch distillation</td>
<td>4.3</td>
<td>Availability of ionic liquid</td>
<td>Yes – as above</td>
</tr>

*Average relative volatility of MeCN in BuOAc
Chart 1. Structures of the cations and anions in the ionic liquids screened as azeotrope breakers for the MeCN-water system.

**Cations:**

- Imidazolium: \[\text{Im}^+\]
- Pyridinium: \[\text{Py}^+\]
- Pyrrolidinum: \[\text{Pyr}^+\]

**Anions:**

- Bis(trifluoromethyl)sulfonylfluoride: \[\text{NTf}_2^−\]
- Acetate: \[\text{CH}_3\text{COO}^−\]
- Chloride: \[\text{Cl}^−\]
- Bromide: \[\text{Br}^−\]
- Hexafluorophosphate: \[\text{PF}_6^−\]
- Tetrafluoroborate: \[\text{BF}_4^−\]
- Dicyanamide: \[\text{N}^−(\text{CN})_2^−\]
- Tosylate: \[\text{Tos}^−\]
Figure Captions

Figure 1. Comparison between the COSMO σ-profiles and σ-surfaces for water, MeCN, hexane and 1-(N-methyl-2-pyrrolidinyl)ethanol.

Figure 2: Liquid-liquid equilibria for the MeCN+water+toluene system at 20 °C determined from NMR analysis and COSMO-RS simulation and compared with literature values.50

Figure 3: Residue curve maps for (a) MeCN-water-MTBE and (b) MeCN-water-N-propyl acetate generated using UNIFAC in Aspen Plus.

Figure 4. Experimental set-up used to measure the VLE of the MeCN+water+IL system.

Figure 5. Experimental and COSMO-RS predicted VLE for the MeCN-water system with 0.3 mole fraction [P6,6,6,14][Cl] entrainer compared with the MeCN-water system with no entrainer obtained in this study and from literature.55

Figure 6. COSMO σ-surfaces for the anions [OTf]−, [BF4]− and [NTf2]−. The anions are ranked according to their ability to break the MeCN-water azeotrope as determined from the screening results.

Figure 7. Experimental and COSMO-RS predicted VLE for the MeCN-water system with 0.3 mole fraction [C8mim][Cl] entrainer compared with the MeCN-water system with no entrainer.

Figure 8. Experimental and COSMO-RS predicted VLE for the MeCN-water system with 0.3 mole fraction [N2,2,2,8][NTf2] entrainer compared with the MeCN-water system with no entrainer.
